Brain purpura (pericapillary encephalorrhagia), incorrectly referred to as “hemorrhagic encephalitis,” consists of multiple petechial hemorrhages scattered throughout the white matter of the brain. The clinical picture is that of a diffuse encephalopathy, but diagnosis is essentially pathologic. Blood does not appear in the CSF, and the condition should not be confused with a stroke. It is virtually impossible to establish the diagnosis during life, but the pathologic appearance is unique and highly characteristic. The lesions in brain purpura are always small, 0.1 to 2.0 mm in diameter, and are confined to the white matter, particularly the corpus callosum, centrum ovale, and middle cerebellar peduncles. Each lesion is situated around a small blood vessel, usually a capillary. In this para-adventitial area, both the myelin and axis cylinders are destroyed, and the lesion is usually though not always hemorrhagic. Fibrin exudation, perivascular and meningeal infiltrates of inflammatory cells, and widespread necrosis of tissue are not observed. In these respects brain purpura differs fundamentally from acute necrotizing hemorrhagic encephalitis. Usually the patient has become stuporous and comatose without focal neurologic signs, and the CSF is normal. The etiology of brain purpura is quite obscure. It may complicate viral pneumonia, uremia, arsenical intoxication, and, rarely, metabolic encephalopathy and sepsis, or there may be no associated disease.

Inflammatory diseases of arteries and veins, especially polyarteritis nodosa, lupus erythematosus, and moyamoya disease, are occasionally associated with cerebral hemorrhage. Rupture of a vessel in these circumstances may be on the basis of hypertension or local vascular disease, and bleeding nearly always occurs into brain tissue rather than into the subarachnoid space. Rarely, intracranial dissection of an artery (usually the vertebral) may allow some blood to escape into the subarachnoid space.

The other rare types of hemorrhage, listed in [Table 34-6](#), are self-explanatory.

Hemorrhages of *intraspinal* origin, all of them rare, may be the result of trauma, AVM (the usual cause of nontraumatic hematomyelia), anterior spinal artery aneurysms, or bleeding into tumors. Spinal subarachnoid hemorrhage from an AVM may simulate an intracranial subarachnoid hemorrhage, causing a stiff neck, head-ache, and even subhyaloid hemorrhages. Subarachnoid hemorrhage in which interscapular or neck pain predominates should raise the suspicion of an aneurysm of the anterior spinal artery or of a spinal AVM or cavernous angioma. Angiographic study of the radicular spinal vessels and the origins of the anterior spinal arteries from the vertebral arteries may disclose the source of bleeding. Extradural and subdural spinal extravasations may be *spontaneous* (sometimes in relation to rheumatoid arthritis) but are far more often due to trauma, anticoagulants, or both. Extradural spinal hemorrhage causes the rapid evolution of paraplegia or quadriplegia; diagnosis must be prompt if function is to be salvaged by surgical drainage of the hematoma. These are discussed further in [Chap. 44](#).

HYPERTENSIVE ENCEPHALOPATHY

Clinical Features This is the term applied to a relatively rapidly evolving syndrome of severe hypertension in association with headache, nausea and vomiting, visual disturbances, confusion, and—in advanced cases—stupor and coma. Multiple seizures are frequent and may be more marked on one side of the body than the other.

These symptoms of diffuse cerebral disturbance may be accompanied by focal or lateralizing neurologic signs, either transitory or lasting, which should always suggest cerebral hemorrhage or infarction, i.e., the more common cerebrovascular complications of severe chronic hypertension. A clustering of multiple microinfarcts and petechial hemorrhages (the basic neuropathologic changes in hypertensive encephalopathy) in one region may rarely result in a mild hemiparesis, aphasia, or rapid failure of vision (usually due to retinal lesions). By the time the neurologic manifestations appear, the hypertension has usually reached the malignant stage, with diastolic pressures above 125 mmHg, retinal hemorrhages, exudates, papilledema (*hypertensive retinopathy* grade IV), and evidence of renal and cardiac disease. However, we have seen instances of encephalopathy at lower pressures, especially if the hypertension has been abrupt in onset (see below). The term *hypertensive encephalopathy* should be reserved for the above syndrome and should not be used to refer to chronic recurrent headaches, dizziness, epileptic seizures, TIAs, or strokes, which often occur in association with high blood pressure.

Hypertensive encephalopathy may complicate hypertension from any cause (chronic renal disease, renal artery stenosis, acute glomerulonephritis, acute toxemia, pheochromocytoma, Cushing syndrome), cocaine, or administration of drugs such as aminophylline or phenylephrine, but it occurs most often in patients with rapidly worsening “essential” hypertension. In *eclampsia* and *acute renal disease* and particularly in children, encephalopathic symptoms may develop at blood pressure levels considerably lower than those of hypertensive encephalopathy of “essential” type. In eclampsia, the retinal and cerebral lesions are the same as those that complicate malignant nephrosclerosis; in both there is also failure of autoregulation of the cerebral arterioles. In the pathogenesis of pre-eclampsia, inhibition of an endothelium-derived relaxing factor by hemoglobin has been postulated by Sarrel and colleagues.

Laboratory Features In many but not all the cases, the CSF pressure and protein values are elevated, the latter to more than 100 mg/dL in some instances. Lowering of the blood pressure with hypotensive drugs may reverse the picture in a day or two. In the past, when effective antihypertensive drugs were not available, the outcome was often fatal. The BUN is only slightly elevated except in cases of renal failure, and the usual patient is not uremic.

Hypertensive encephalopathy is marked by characteristic changes on CT scanning and MRI. The radiologic findings are often misinterpreted as large areas of infarction or demyelination, but their tendency to normalize over several weeks is remarkable. As summarized by Hauser and coworkers, the main change is bilaterally increased T2 signal intensity in the white matter on MRI and reduced density (edema) on CT, usually concentrated in the posterior part of the hemispheres ([Fig. 34-27](#)). These imaging characteristics are due to an accumulation of fluid, but—unlike the edema in trauma, neoplasm, or stroke—there is little or no mass effect and the water does not tend to course along white matter tracts such as the corpus callosum. In addition, scattered cortical lesions occur in a watershed distribution and probably correspond to small infarctions. These same CT findings in the white matter and cortex also occur in eclampsia, which is a special form of hypertensive encephalopathy ([Fig. 34-28](#)).

Figure 34-27 Hypertensive encephalopathy in a 55-year-old woman with headache and a single seizure. The characteristic changes of excess water in large regions of the white matter are seen on the CT scan (left panel) and in T-2 weighted MRI image (right panel). The areas of signal change are associated with little mass effect and tend to be concentrated in the posterior regions of the brain. Other small cortical and subcortical lesions are common in watershed areas. The same change may occur in eclampsia.

Figure 34-28 MRI T2 signal changes in eclampsia. Most of the vascular changes and edema are situated in the cortical watershed distributions between the middle and an anterior cerebral arteries. These imaging findings were transient as was mild signal change in the occipital subcortical regions, the latter being typical of hypertensive encephalopathy, as in [Fig. 34-27](#).

Pathophysiology Neuropathologic examination may reveal a rather normal-looking brain, but in some cases cerebral swelling, hemorrhages of various sizes, or both will be found. A cerebellar pressure cone reflects an increased volume of tissue and increased pressure in the posterior fossa; in some instances lumbar puncture appears to have precipitated fatalities. Microscopically there are widespread minute infarcts in the brain (with a predilection for the basis pontis), the result of fibrinoid necrosis of the walls of arterioles and capillaries and occlusion of their lumens by fibrin thrombi ([Chester et al](#)). This is often associated with zones of cerebral edema. Similar vascular changes are found in other organs, particularly in the retinae and kidneys.

Volhard originally attributed the symptoms of hypertensive encephalopathy to vasospasm. This notion was reinforced by Byrom, who demonstrated, in rats, a segmental constriction and dilatation of cerebral and retinal arterioles in response to severe hypertension. However, the observations of Byrom and of others indicate that overdilatation of the arterioles (which have lost their adaptive capacity), rather than excessive constriction, may be responsible for the necrosis of the vessel wall (see reviews of [Auer](#) and of [Chester et al](#)). The brain edema appears to be the result of active exocytosis of water rather than simply a passive leak from vessels subjected to high pressures.

Treatment The standard treatment consists of measures that promptly reduce arterial blood pressure, but they must be used cautiously; a safe target would be 150/100 mmHg. One may use intravenous sodium nitroprusside, 0.5 to 0.8 µg/kg per minute; a calcium channel blocker such as nifedipine, 10 to 20 mg sublingually; or intravenous beta-adrenergic blockers (labetalol, 20 to 40 mg intravenously followed by an infusion at 2 mg/min, and esmolol are favored). These must be followed by a longer-acting antihypertensive agent such as an angiotensin-converting enzyme inhibitor or a calcium channel blocker. If there is already evidence of brain edema and increased intracranial pressure, dexamethasone, 4 to 6 mg every 6 h, is usually added, but its effect and the use of hyperosmolar therapy have not been studied systematically; our clinical impression is that they have little effect.

Diffuse and Focal Cerebral Vasospasm A reduction in the caliber of the basal vessels and their proximal branches is a well-known complication of subarachnoid hemorrhage as described on page 891. Vasospasm has also been implicated in migraine and migrainous stroke and as an explanation for TIAs, but with little supportive evidence. Some degree of attenuation of large cerebral vessels is observed in hypertensive encephalopathy, in eclampsia, and with adrenergic drug use (e.g., phenylpropanolamine, cocaine), but the role of the vascular changes in causing strokes has never been clear. The problem of stroke with migraine, which has an uncertain relationship to vasospasm, is discussed on page 184.

In addition, Call and colleagues have described an idiopathic widespread segmental vasospasm of cerebral vessels that is characterized by severe headache and fluctuating TIA-like episodes. The middle cerebral artery and its branches are mainly affected; the angiographic appearance may be mistaken for arteritis. A number of similar cases have been described, and we have seen several that result in strokes, at times with a posterior leukoencephalopathy that is similar to hypertensive encephalopathy. Sometimes the headache is minimal. The nature of this condition and of a similar state of diffuse vasospasm is unknown. A relationship to hypertensive encephalopathy or to delayed postpartum eclampsia has been suggested, because of the aforementioned white matter changes and the observation of widespread vasospasm in eclamptic women. The patients we have seen with this process, after several weeks of fluctuating focal neurological symptoms and headache, have recovered completely or nearly so. In all likelihood, several disorders cause this type of vasculopathy. Calcium channel blockers or corticosteroids have been prescribed, but their effectiveness cannot be determined.

INFLAMMATORY DISEASES OF BRAIN ARTERIES

Infectious Vasculitis

Inflammatory diseases of the blood vessels of infectious origin and their effects upon the nervous system have been considered in detail in [Chap. 32](#). There it was pointed out that meningovascular syphilis, tuberculous meningitis, fungal meningitis, and the subacute (untreated or partially treated) forms of bacterial meningitis may be accompanied by inflammatory changes and occlusion of the cerebral arteries or veins. Occasionally, in syphilitic, cryptococcal, and tuberculous meningitis, a stroke may be the first clinical sign of meningitis, but more often it develops well after the meningeal symptoms are established. The nature of the cerebral vasculitis that may rarely accompany AIDS is unknown.

Typhus, schistosomiasis, mucormycosis, malaria, and trichinosis are rare causes of inflammatory arterial disease which, unlike the above, are not secondary to meningeal infections. In *typhus and other rickettsial diseases*, capillary and arteriolar changes and perivascular inflammatory cells are found in the brain; presumably they underlie the seizures, acute psychoses, cerebellar syndromes, and coma that characterize the neurologic disorder in these diseases. The internal carotid artery may be occluded in diabetic patients as part of the orbital and cavernous sinus infections with *mucormycosis*. In *trichinosis*, the cause of the cerebral symptoms has not been established. Parasites have been found in the brain; in one of our cases the cerebral lesions were produced by bland emboli arising in the heart and related to a severe myocarditis. In *cerebral malaria*, convulsions, coma, and sometimes focal symptoms appear to be due to the blockage of capillaries and precapillaries by masses of parasitized red blood corpuscles. Schistosomiasis may implicate cerebral or spinal arteries. These diseases are discussed further in [Chap. 32](#).

Noninfectious Inflammatory Diseases of Cranial Arteries

Included under this heading is a diverse group of arteritides that have little in common except their tendency to involve the cerebral vasculature. One subgroup includes the *giant-cell arteritides*—extracranial (temporal) arteritis; granulomatous arteritis of the brain; and aortic branch arteritis, one form of which is known as Takayasu disease, all discussed on the following pages.

A second group includes polyarteritis nodosa, the Churg-Strauss type of arteritis, Wegener granulomatosis, systemic lupus erythematosus, Behçet disease, postzoster arteritis, and AIDS arteritis, as already mentioned. Immunologic studies have shown that in most of these diseases there is an abnormal deposit of complement-fixing immune complex on the endothelium, leading to inflammation, vascular occlusion, or rupture with hemorrhage. The initial event is thought in some cases to be evoked by a virus, bacterium, or drug. It is postulated by some immunologists that in the *granulomatous arteritides*, a different mechanism is operative—that an exogenous antigen induces antibodies that attach to the primary target (the vessel wall) as immune complexes, damage it, and attract lymphocytes and mononuclear cells. The giant cells form around remnants of the vessel wall (elastic tissue, etc.). An acute necrotizing cerebral angiitis—which may be idiopathic, sometimes complicates ulcerative colitis, and responds to treatment with prednisone and cyclophosphamide—may also belong in this category. The special case of angiocentric lymphoma (neoplastic angioendotheliosis), which simulates a cerebral vasculitis, is discussed in [Chap. 31](#).

Temporal Arteritis (Giant-Cell Arteritis, Cranial Arteritis; See also pages 193–194) In this affliction, not uncommon among elderly persons, arteries of the external carotid system, particularly the temporal branches, are the sites of a subacute granulomatous inflammatory exudate consisting of lymphocytes and other mononuclear cells, neutrophilic leukocytes, and giant cells. The most severely affected parts of the artery usually become thrombosed. The sedimentation rate is characteristically elevated above 80 mm/h and sometimes exceeds 120 mm/h, but a few cases occur with values below 50 mm/h.

Headache or head pain is the chief complaint, and there may be severe pain, aching, and stiffness in the proximal muscles of the limbs associated with a markedly elevated sedimentation rate. Thus the clinical picture overlaps that of *polymyalgia rheumatica* (pages 230 and 1572). Other less frequent systemic manifestations include fever, anorexia and loss of weight, malaise, anemia, and a mild leukocytosis. Instances of dementia and other neurologic illnesses that have been described in the literature seem to us coincidental.

Occlusion of branches of the ophthalmic artery, resulting in blindness in one or both eyes, is the main complication, occurring in over 25 percent of patients. In the most extreme form, the optic nerve head can be seen to be infarcted, with papilledema and visual loss. In a few cases this is preceded by transient visual loss simulating a TIA. Occasionally the arteries of the ocular nerves are involved, causing an ophthalmoplegia. Rarely, an arteritis of the aorta and its major branches—including the carotid, subclavian, coronary, and femoral arteries—is found at postmortem examination. Significant inflammatory involvement of intracranial arteries is uncommon, perhaps because of a relative lack of elastic tissue, but strokes do occur rarely on the basis of occlusion of the internal carotid or vertebral arteries.

The diagnosis should be suspected in elderly patients who develop severe, persistent headache and elevation of the sedimentation rate; it depends on finding a tender, thrombosed, or thickened cranial artery and demonstration of the lesion in a biopsy. The procedure is innocuous and the diagnosis may require that both sides be sampled because of the patchy distribution of granulomatous lesions. Schmidt and colleagues have reported that the diagnosis can often be made with duplex ultrasonography. In 22 of 30 cases, a dark halo, probably reflecting edema, surrounded the temporal artery; 6 cases showed either occlusion or stenosis of the artery; there were no false-positive tests. A considerable length of the temporal artery can be insonated by this technique, a particularly useful feature in a process that affects the vessel segmentally. From our limited experience, this test can be recommended before resorting to a biopsy. The arteritic changes may also be revealed by arteriography of the external carotid arteries.

The administration of prednisone, 50 to 75 mg/day, provides striking relief of the headache and polymyalgic symptoms within days and sometimes within hours and also prevents blindness. The medication must be given in very gradually diminishing doses for at least several months or longer, guided by the symptoms and the sedimentation rate. The latter begins to drop within days but seldom falls below 25 mm/h.

Intracranial Granulomatous Arteritis Scattered examples of a small-vessel giant-cell arteritis of undetermined etiology in which only brain vessels are affected have come to our notice over the years. The clinical state has taken diverse forms, sometimes presenting as a low-grade, nonfebrile meningitis with sterile CSF, followed by infarction of one or several parts of the cerebrum or cerebellum. In other cases it has masqueraded as a cerebral tumor, evolving over a period of weeks, or as a viral encephalitis or an unusual dementia. Severe headaches, focal cerebral or cerebellar signs of gradual (seldom stroke-like) evolution, confusion with memory loss, pleocytosis and elevated CSF protein, and papilledema as a result of increased intracranial pressure (in about half the cases) constitute the most frequently encountered syndrome. The symptoms usually persist for several months.

In only about half the patients can the diagnosis be made by angiography, which demonstrates an irregular narrowing and blunt ending of small cerebral arteries. CT scanning and MRI show multiple irregular white matter changes and small cortical lesions. Occasionally the white matter abnormalities become confluent and the radiologic appearance simulates Binswanger disease or hypertensive encephalopathy. Tissue excised during an operation (or brain biopsy) for a suspected brain tumor, lymphoma, or white matter disease has clarified the problem in some cases, and in others the diagnosis has been made only at autopsy, the findings coming as a distinct surprise.

The affected vessels are in the 100- to 500- μ m range and are surrounded and infiltrated by lymphocytes, plasma cells, and other mononuclear cells; giant cells are distributed in small numbers in the media, adventitia, or perivascular connective tissue. Infarction of tissue can be traced to thrombosis. The meninges are variably infiltrated with inflammatory cells. Sometimes only a part of the brain has been affected—in one of our cases the cerebellum, in another a frontal lobe and the opposite parietal lobe.

The disease raises the question of sarcoidosis, which is sometimes limited to the nervous system, of intravascular lymphoma, or of the polyarteritis (allergic

granulomatous angiitis) described by Churg and Strauss. Unlike these diseases, however, the lungs and other organs are spared; there is no eosinophilia, increase in sedimentation rate or in antineutrophil cytoplasmic antibodies (ANCA), or anemia. Brain lymphoma of the intravascular type and multiple sclerosis are also diagnostic considerations, from both a clinical and a radiologic perspective. Some patients with isolated central nervous system (CNS) angiitis (those presenting as an aseptic meningitis with multiple infarcts) have responded dramatically to corticosteroid and cyclophosphamide therapy (Moore).

Aortic Branch Disease (Takayasu Disease, Occlusive Thromboangiopathy) This is a nonspecific arteritis involving mainly the aorta and the large arteries arising from its arch. It is similar in many ways to giant-cell arteritis except for its propensity to involve the proximal rather than the distal branches of the aorta. Most of the patients have been young Asian women, but there are scattered reports of cases from the United States, Latin America, and eastern Europe. The exact etiology has never been ascertained, but an autoimmune mechanism is suspected.

Constitutional symptoms such as malaise, fever, anorexia, weight loss, and night sweats usually introduce the disease. The erythrocyte sedimentation rate is elevated in the early and active stages. Later there is evidence of occlusion of the innominate, subclavian, carotid, vertebral, and other arteries. The affected arteries no longer pulsate, hence the alternative term *pulseless disease*. However, it should be noted that the Occidental pulseless disease is usually due to atherosclerosis. When renal arteries are involved, hypertension may result, and coronary occlusion is often fatal. Involvement of the pulmonary artery may lead to pulmonary hypertension. Coolness of the hands and weak radial pulses are common indicators of the disease and headaches are frequent. Blurring of vision, especially upon activity, dizziness, and hemiparetic and hemisensory syndromes are the usual neurologic manifestation ([Lupi-Herrera et al](#)). Several authors have emphasized the frequency of postural symptoms as well as the relative infrequency of major strokes, despite multiple TIA-like spells.

Pathologic studies disclose a periarteritis, often with giant cells and reparative fibrosis. Many of the patients die in 3 to 5 years. According to Ishikawa and colleagues, the administration of corticosteroids in the acute inflammatory stage of the disease improves the prognosis. Reconstructive vascular surgery has helped some of the patients in the later stages of the disease.

Polyarteritis (Periarteritis) Nodosa In this disorder there is an inflammatory necrosis of arteries and arterioles throughout the body. The lungs are usually spared, however, which is the basis of distinguishing this form of vasculitis from the allergic granulomatous angiitis of Churg and Strauss, mentioned above. The vasa nervorum are frequently involved by the lesions of polyarteritis, giving rise to a mononeuropathy multiplex or to a symmetrical axonal type of polyneuropathy (see page 1400). Involvement of the CNS is unusual (occurring in fewer than 5 percent of cases) and takes the form of widespread microinfarcts; macroscopic infarction is a rarity. The clinical manifestations vary: included are headache, confusion and fluctuating cognitive disorders, convulsions, hemiplegia, and brainstem signs. We have also observed acute spinal cord lesions. The CNS lesions and brain hemorrhage are rare and usually occur in a setting of renal hypertension.

Wegener Granulomatosis This is a rare disease of unknown cause, affecting adults as a rule and predominating slightly in males. A subacutely evolving vasculitis with necrotizing granulomas of the upper and lower respiratory tracts followed by necrotizing glomerulonephritis are its main features. Neurologic complications come later in one-third to one-half of cases and take two forms: (1) a peripheral neuropathy either in a pattern of polyneuropathy or, far more frequently, in a pattern of mononeuropathy multiplex (page 1427) and (2) multiple cranial neuropathies as a result of direct extension of the nasal and sinus granulomas to upper cranial nerves and of pharyngeal lesions to the lower nerves (see page 1460). The basilar parts of the skull may be eroded, with spread of granuloma to the cranial cavity and more remote parts. Cerebrovascular events, seizures, and cerebritis are less common neurologic complications. Spastic paraparesis, temporal arteritis, Horner syndrome, and papilledema have been observed but are rare (see [Nishino et al](#)). The orbits are involved in 20 percent of patients, and lesions here simulate the clinical and radiologic appearance of orbital pseudotumor, cellulitis, or lymphoma. Pulmonary granulomas, usually asymptomatic but evident on a chest film, are also common. The vasculitis implicates both small arteries and veins. There is a fibrinoid necrosis of their walls and an infiltration by neutrophils and histiocytes. The sedimentation rate is elevated, as are the rheumatoid and antiglobulin factors. The presence in the blood of antineutrophil cytoplasmic antibodies (c-ANCA) has been found to be relatively specific and highly sensitive for Wegener disease (it may also be found in intravascular lymphoma).

A high degree of therapeutic success in this formerly fatal disease has been achieved by the use of cyclophosphamide, chlorambucil, or azathioprine. Cyclophosphamide in oral doses of 1 to 2 mg/kg per day has cured 90 to 95 percent of the cases. In acute cases, rapidly acting steroids—prednisolone, 50 to 75 mg/day—should be given in conjunction with the immunosuppressant drug(s).

Systemic Lupus Erythematosus Involvement of the nervous system is an important aspect of this disease. In the series reported by Johnson and Richardson, the CNS was involved in 75 percent of cases. Disturbances of mental function including alteration of consciousness, seizures, and signs referable to cranial nerves are the usual neurologic manifestations; most often they develop in the late stages of the disease, but they may occur early and may be mild and transient. Hemiparesis, paraparesis, aphasia, homonymous hemianopia, movement disorders (chorea), and derangements of hypothalamic function occur but have been infrequent in our experience. Larger infarcts are usually traceable to emboli from Libman-Sacks endocarditis. In some instances the CNS manifestations resemble multiple sclerosis, especially when there is an optic neuritis and myelopathy. The presence of serum antinuclear antibodies is of help in the diagnosis of lupus erythematosus but in itself does not establish the diagnosis. The CSF is entirely normal or shows only a mild lymphocytic pleocytosis and increase in protein content, although in some patients—primarily those with peripheral neuropathy and myelopathy—the protein content may be greatly increased.

Most of the neurologic manifestations can be accounted for by widespread microinfarcts in the cerebral cortex and brainstem; these, in turn, are related to destructive and proliferative changes in arterioles and capillaries. The acute lesion is subtle; it is not a typical fibrinoid necrosis of the vessel wall, like that in hypertensive encephalopathy, and there is no cellular infiltration. Attachment of immune complexes to the endothelium is the postulated mechanism of vascular injury. Thus, the changes do not represent a vasculitis in the strict sense of the word. Other neurologic manifestations are related to hypertension, which frequently accompanies the disease and may precipitate cerebral hemorrhage; to endocarditis, which may give rise to cerebral embolism; to thrombotic thrombocytopenic purpura, which commonly complicates the terminal phase of the disease ([Devinsky et al](#)); and to treatment with corticosteroids, which may precipitate or accentuate muscle weakness, seizures, and psychosis. In other cases, steroids appear to improve these neurologic manifestations.

Arteritis Symptomatic of Underlying Systemic Disease Both AIDS and drug abuse (mainly cocaine) have been associated with a cerebral vasculitis that is similar to polyarteritis nodosa. With respect to the former, if deep infarctions have occurred, a basal meningitis due to tuberculosis, cryptococcosis, or syphilis with occlusion of penetrating vessels must always be entertained. Drug-induced vasculitis is difficult to distinguish from a more common state of focal vasospasm that may also be induced by these same agents. Finally, a true cerebral or spinal cord vasculitis can rarely be found in association with systemic lymphoma, particularly with Hodgkin disease. The nature of this process is indeterminate but may be related to the deposition of circulating immune complexes in the walls of cerebral vessels.

Another type of small-vessel arteritis occurs as a hypersensitivity phenomenon. Often it is associated with an allergic skin lesion (Stevens-Johnson vasculopathy or a leukocytoclastic vasculitis). The clinical picture does not resemble that of polyarteritis nodosa, but the central or peripheral nervous system is affected in rare instances. The response to corticosteroids is excellent.

Yet another ill-defined form of vasculitis has been described by Susac and colleagues. This is a microangiopathy affecting mainly the brain and retina. Psychiatric symptoms, dementia, sensorineural deafness, and impairments of vision are the clinical manifestations. Funduscopy (multiple retinal artery branch occlusions) and arteriography provide evidence of vasculopathy. The patients seem to respond to steroid therapy. Only biopsy material has been examined.

Behçet Disease This disorder may suitably be considered here, since it is essentially a chronic, recurrent vasculitis, involving small vessels, with prominent neurologic manifestations. It is most common in Turkey, where it was first described, in other Near East countries, and in Japan, but it occurs throughout Europe and North America, affecting men more often than women. The disease was originally distinguished by the triad of relapsing iridocyclitis and recurrent oral and genital ulcers, but it is now recognized to be a systemic disease with a much wider range of symptoms, including erythema nodosum, thrombophlebitis, polyarthritides, ulcerative colitis, and a number of neurologic manifestations, some of them encephalitic or meningitic in nature. The most reliable diagnostic criteria, according to an International Study Group that assembled data on 914 cases from 12 medical centers in 7 countries, were recurrent aphthous or herpetiform oral ulceration, recurrent genital ulceration, anterior or posterior uveitis, cells in the vitreous or retinal vasculitis, and erythema nodosum or papulopustular lesions.

The nervous system is affected in about 30 percent of patients with Behçet disease ([Chajek and Fainaru](#)); the main manifestations are recurrent meningoencephalitis, cranial nerve (particularly abducens) palsies, cerebellar ataxia, and corticospinal tract signs. There may be episodes of diencephalic and brainstem dysfunction resembling minor strokes. A few postmortem examinations have related these stroke-like episodes to small, appropriately placed foci of necrosis along with perivascular and meningeal infiltration of lymphocytes. There may also be cerebral venous thrombosis. The neurologic symptoms usually have an abrupt onset and are accompanied by a brisk pleocytosis (lymphocytes or neutrophils may predominate), along with elevated protein but normal glucose values (one of our cases had 3000 neutrophils per cubic millimeter at the onset of an acute meningitis). As a rule, neurologic symptoms clear completely in several weeks, but they have a tendency to recur, and some patients are left with persistent neurologic deficits. Rarely, the clinical picture is that of a progressive confusional state and dementia

(see the reviews of [Alema](#) and of [Lehner and Barnes](#) for detailed accounts).

The cause of Behçet disease is unknown. We have been unable to detect virus particles in the margins of an ulcerative mouth lesion. A pathergy skin test—the formation of a sterile pustule at the site of a needle prick—is listed as an important diagnostic test by the International Study Group, but we have found it to be of questionable value. Administration of corticosteroids has been the usual treatment, on the assumption of an autoimmune etiology. Since the episodes of disease naturally subside and recur, evaluation of treatment is difficult.

OTHER FORMS OF CEREBROVASCULAR DISEASE

Thrombosis of Cerebral Veins and Venous Sinuses

Thrombosis of the cerebral venous sinuses, particularly of the superior sagittal or lateral sinus and the tributary cortical and deep veins, gives rise to a number of important neurologic syndromes. Cerebral vein thrombosis may develop in relation to infections of the adjacent ear and paranasal sinuses or to bacterial meningitis, as described in [Chap. 32](#). More common is bland venous occlusion resulting from one of the many hypercoagulable states that are listed below.

Occlusion of cortical veins that are tributaries of the dural sinuses takes the form of a venous infarctive stroke. Diagnosis is difficult except in certain clinical settings known to favor the occurrence of venous thrombosis, such as the taking of birth control pills or postpartum and postoperative states, which are often characterized by thrombocytosis and hyperfibrinogenemia; hypercoagulable states in cancer, cyanotic congenital heart disease; cachexia in infants; sickle cell disease; antiphospholipid antibody syndrome, factor V Leiden mutation, protein S or C deficiency, antithrombin III deficiency, resistance to activated protein C; primary or secondary polycythemia and thrombocythemia; and paroxysmal nocturnal hemoglobinuria. The study by Martinelli and colleagues, alluded to earlier in the chapter, attributes 35 percent of cases to a mutation in the factor V or the prothrombin gene. A few cases will follow head injury or remain unexplained.

A stroke in a patient suffering from any one of these conditions should suggest venous thrombosis, though in some instances—e.g., postpartum strokes—arteries are occluded as often as veins. The somewhat slower evolution of the clinical syndrome, the presence of multiple cerebral lesions not in typical arterial territories, and its greater epileptogenic and hemorrhagic tendency favor venous over arterial thrombosis. Averback, who reported seven cases of venous thrombosis in young adults, has emphasized the diversity of the clinical causes. Two of his patients had carcinoma of the breast and one had ulcerative colitis.

Nevertheless, certain syndromes occur with sufficient regularity to suggest thrombosis of a particular vein or sinus. The signature features of *thrombosis of cortical veins* are the presence of large superficial (cortex and subjacent white matter) hemorrhagic infarctions and a marked tendency to seizures. In the case of *sagittal sinus thrombosis*, intracranial hypertension with headache, vomiting, and papilledema may constitute the entire syndrome or may be conjoined with hemorrhagic infarction; indeed, this is the main consideration in the differential diagnosis of pseudotumor cerebri ([Chap. 30](#)). The characteristic CT appearance of sagittal sinus thrombosis is described below. To the extent that most cortical vein thromboses originate from clots in the sagittal sinus, the hemorrhagic infarctions tend to be parasagittal, characteristically biparietal, and less often bifrontal, with headache, paraparesis or hemiparesis predominantly of the leg, or aphasia. The variable location of the infarctions reflects the inconstant location of the main surface cerebral veins (named for Labbé and for Trolard). Isolated cortical vein thrombosis is far less frequent and, according to Jacobs and colleagues, causes partial seizures and headache without signs of intracranial hypertension.

As pointed out in [Chap. 13](#), marked chemosis and proptosis—with affection of cranial nerves III, IV, VI, and the ophthalmic division of V—are indicative of *anterior cavernous sinus thrombosis* (see [Fig. 34-29](#)). *Posterior cavernous sinus thrombosis*, spreading to the inferior petrosal sinus, may cause palsies of cranial nerves VI, IX, X, and XI without proptosis, and involvement of the *superior petrosal sinus* may be accompanied by a fifth nerve palsy. Increased intracranial pressure without ventricular dilatation occurs with thrombosis of the superior sagittal sinus, the main jugular vein, and the lateral sinus or torcula.

Figure 34-29 Diagram of the cavernous sinus: (1) optic chiasm; (2) oculomotor nerve; (3) cavernous sinus; (4) trochlear nerve; (5) internal carotid artery; (6) ophthalmic nerve; (7) abducens nerve; (8) maxillary nerve. (From Krayenbühl and Yasargil by permission.)

The common radiologic picture that results from occlusion of the superior sagittal sinus is of superficial paramedian parietal hemorrhagic infarction, often bilateral. In the case of CT scan with contrast infusion, a lack of dye in the posterior empty sagittal sinus can be observed with careful adjustment of the viewing window (“empty delta sign”). The spinal fluid pressure is increased and the fluid may be slightly sanguinous. Lateral sinus thrombosis causes hemorrhagic infarction of the temporal lobe convexity, usually with considerable vasogenic edema. The enhanced CT scan, arteriography (venous phase), and MR venography greatly facilitate diagnosis by directly visualizing the venous occlusion. Once a venous thrombosis becomes established, the tributary veins take on a “corkscrew” appearance.

Anticoagulant therapy beginning with heparin for several days, followed by warfarin, and combined with antibiotics if the venous occlusion is infectious (it rarely is in recent times), has been lifesaving in some cases, but the overall mortality rate remains high due to large hemorrhagic venous infarctions in 10 to 20 percent of cases. The trial by Einhaupl and colleagues has settled the question of therapy in favor of aggressive anticoagulation. Thrombolytic therapy by local venous or systemic infusion has also been successful in small series of cases, such as the 5 patients treated with urokinase and heparin by DiRocco and colleagues, but this has not been subjected to a systematic study. We have reserved thrombolysis for extreme cases with stupor or coma and greatly raised CSF pressure.

Marantic Endocarditis and Cerebral Embolism

Sterile vegetations, referred to also as *terminal or nonbacterial thrombotic endocarditis*, consist of fibrin and platelets and are loosely attached to the mitral and aortic valves and contiguous endocardium. They are a common source of cerebral embolism (almost 10 percent of all instances of cerebral embolism according to Barron et al, but lower in the experience of others). In almost half the patients, the vegetations are associated with a malignant neoplasm; the remainder occur in patients debilitated by other diseases ([Biller et al](#)). Except for the setting in which it occurs, marantic embolism has no distinctive clinical features that permit differentiation from cerebral embolism of other types. The apoplectic nature of marantic embolism distinguishes it from the usual forms of tumor metastases. The hazards of using anticoagulants in gravely ill patients with widespread malignant disease probably outweigh the benefits from this treatment, but drugs that prevent platelet aggregation have not been studied systematically for this condition.

The lesions of small cerebral arteries formerly observed in patients with rheumatic heart disease and referred to as *rheumatic arteritis* have not been well characterized clinically or pathologically. The vascular lesions and the microinfarcts that accompany them are probably manifestations of diffuse cerebral embolism. Any relationship to the lesion of Sydenham chorea is entirely speculative.

Stroke as a Complication of Hematologic Disease

The brain is involved in the course of many hematologic disorders, some of which have already been mentioned. A number of the better-characterized ones are discussed here.

Antiphospholipid Antibodies This condition, in which migraine, thrombocytopenia, TIAs, or stroke occurs in young adults, has already been alluded to under

“Strokes in Children and Young Adults.” It is in some instances related to lupus erythematosus vasculopathy. The most frequent neurologic abnormality is a TIA, usually taking the form of amaurosis fugax, with or without retinal arteriolar or venous occlusion ([Digre et al](#)). Stroke-like phenomena are more frequent in patients who also have migraine, hyperlipidemia, and antinuclear antibodies and in those who smoke or take birth control pills. Almost one-third of the 48 patients reported by Levine and associates had thrombocytopenia and 23 percent had a false-positive VDRL test. Some of the phospholipids with which the antibodies react are shared with clotting factors, particularly prothrombin or annexin, as well as with the “lupus anticoagulant” (a cardiolipin-glycoprotein complex). These antibodies are circulating serum polyclonal immunoglobulins (IgG, IgM, IgA). The vascular lesions are mainly in the cerebral white matter and are infarcts, seen well with MRI. Angiography reveals occlusions of arteries at unusual sites ([Brey et al](#)). The mechanism of stroke is not entirely clear and may derive from emboli originating on mitral valve leaflets similar to nonbacterial thrombotic ([Libman-Sacks](#)) endocarditis; alternatively, and more likely in our view, these are due to noninflammatory in situ thrombosis of medium-sized cerebral vessels as suggested by limited pathologic material ([Briley et al](#)).

The *Sneddon syndrome* consists of deep blue-red lesions of livedo reticularis and livedo racemosa in association with multiple strokes; 126 cases had been reported up to 1992. Most but not all patients have high titers of antiphospholipid antibodies. Although the skin lesions show a noninflammatory vasculopathy with intimal thickening, the pathology of the occlusive disease has not been adequately studied. In a report of 17 such patients by Stockhammer and coworkers, 8 had strokes and MRI showed lesions in 16 of 17 patients. The age of patients with strokes was 30 to 35 years, hence this condition must always be considered in young adults with cerebrovascular disease. Many of the lesions on MRI were small, deep, and multiple. Although there is a tendency for strokes to recur, many of the patients have remained well for years after their stroke. Skin biopsy aids in diagnosis.

Anticoagulants have been used with some benefit in both of these conditions, and Khamashta and colleagues have found that the INR must be maintained close to 3 for effective prevention of stroke. Plasma exchange may be useful in fulminant cases. Aspirin and heparin are favored in women with recurrent fetal loss related to antiphospholipid antibody ([Lockshin and Sammaritano](#)).

Thrombotic Thrombocytopenic Purpura (TTP, Moschcowitz Syndrome) This is yet another uncommon but serious disease of the small blood vessels, observed mainly in young adults. It is characterized pathologically by widespread occlusions of arterioles and capillaries involving practically all organs of the body, including the brain. The nature of the occluding material has not been completely defined. Fibrin components have been identified by immunofluorescent techniques; some investigators have demonstrated disseminated intravascular platelet aggregation rather than fibrin thrombi. TTP arises because of an inhibitor of von Willebrand factor–cleaving protease; the rarer familial form is caused by a constitutional deficiency of the protease.

Clinically, the main features of this disease are fever, anemia, symptoms of renal and hepatic disease, and thrombocytopenia—the latter giving rise to the common hemorrhagic manifestations (petechiae and ecchymoses of the skin, retinal hemorrhages, hematuria, gastrointestinal bleeding, etc.). Neurologic symptoms are practically always present and are the initial manifestation of the disease in about half the cases. Confusion, delirium, seizures, and altered states of consciousness—sometimes remittent or fluctuating in nature—are the usual manifestations of the nervous system disorder and are readily explained by the widespread microscopic ischemic lesions in the brain. Gross infarction was not observed. The recommended treatment is plasma exchange or plasma infusion.

Thrombocytosis and Thrombocythemia These terms refer to an increase of platelets above 800,000 per cubic millimeter. The condition is generally considered to be a form of myeloproliferative disease. In some patients there is an enlarged spleen, polycythemia, chronic myelogenous leukemia, or myelosclerosis. In several of our patients no explanation of the thrombocytosis was found. They presented with recurrent cerebral and systemic thrombotic episodes, often of minor degree and transient. Cytopheresis, to reduce the platelets, and antimetabolic drugs (hydroxyurea) to suppress megakaryocyte formation, are helpful in preventing the neurologic symptoms.

Polycythemia Vera This is a myeloproliferative disorder of unknown cause, characterized by a marked increase in red cell mass (7 to 11 million per cubic millimeter) and blood volume and often by an increase in white cells and platelets as well. This condition must be distinguished from the many secondary or symptomatic forms of polycythemia (erythrocytosis), in which the platelets and white cells remain normal. The slightly increased incidence of thrombosis in primary polycythemia is attributed to the high blood viscosity, engorgement of vessels, and reduced rate of blood flow. The majority of patients with cerebrovascular manifestations have TIAs and small strokes, but on rare occasions we have seen a sagittal sinus thrombosis. The cause of cerebral hemorrhage in this disease is less clear, although a number of abnormalities of platelet function and of coagulation have been described (see [Davies-Jones et al](#)).

A wide variety of bleeding disorders—such as *leukemia*, *aplastic anemia*, *thrombocytopenic purpura*, and *hemophilia*—may also give rise to cerebral hemorrhage. Many rare forms of bleeding disease may be complicated by hemorrhagic manifestations; these have been reviewed by Davies-Jones and colleagues.

Sickle Cell Disease This inherited disease is related to the presence of the abnormal hemoglobin S in the red corpuscles. Clinical abnormalities occur only in patients with sickle cell disease, i.e., with the homozygous state, and not in those with the sickle cell trait, which represents the heterozygous state. The disease, which is practically limited to blacks, begins early in life and is characterized by “crises” of infections (particularly pneumococcal meningitis), pain in the limbs and abdomen, chronic leg ulcers, and infarctions of bones and visceral organs. Ischemic lesions of the brain, both large and small, are the most common neurologic complications, but cerebral, subarachnoid, and subdural hemorrhage may also occur and the vascular occlusions may be either arterial or venous.

Disseminated Intravascular Coagulation (DIC) This is perhaps the commonest and most serious disorder of coagulation affecting the nervous system. The basic process depends on the release of thromboplastic substances from damaged tissue, resulting in the activation of the coagulation process and the formation of fibrin, in the course of which clotting factors and platelets are consumed. Virtually any mechanism that produces tissue damage can result in the release of tissue thromboplastins into the circulation. Thus, DIC complicates a wide variety of clinical conditions—overwhelming sepsis, massive trauma, cardiothoracic surgery, heat stroke, burns, incompatible blood transfusions and other immune complex disorders, diabetic ketoacidosis, leukemia, obstetric complications, cyanotic congenital heart disease, and shock from many causes.

The essential pathologic change in DIC is the occurrence of widespread fibrin thrombi in small vessels, resulting in numerous small infarctions of many organs, including the brain. Sometimes DIC is manifest by a hemorrhagic diathesis in which petechial hemorrhages are situated around small penetrating vessels. In some cases the cerebral hemorrhage is quite extensive, similar to a primary hypertensive hemorrhage. The main reason for the hemorrhage is the consumption of platelets and various clotting factors that occurs during fibrin formation; in addition, fibrin degradation products have anticoagulant properties of their own.

The diffuse nature of the neurologic damage may suggest a metabolic rather than a vascular disorder of the brain. In the absence of a clear metabolic, infective, or neoplastic cause of an encephalopathy, the onset of acute and fluctuating focal neurologic abnormalities or a generalized and sometimes terminal neurologic deterioration during the course of a severe illness should arouse suspicion of DIC, and coagulation factors and fibrin split products should be measured. Platelet counts are invariably depressed and there is evidence of consumption of fibrinogen and other clotting factors, indicated by prolonged prothrombin and partial thromboplastin times.

DIFFERENTIATION OF VASCULAR DISEASE FROM OTHER NEUROLOGIC ILLNESSES

The diagnosis of a vascular lesion rests essentially on recognition of the stroke syndrome; without evidence of this, the diagnosis must always be in doubt. The three criteria by which the stroke is identified should be re-emphasized: (1) the temporal profile of the clinical syndrome, (2) evidence of focal brain disease, and (3) the clinical setting. Definition of the temporal profile requires a clear history of the premonitory phenomena, the mode of onset, and the evolution of the neurologic disturbance in relation to the patient's medical status. An inadequate history is the most frequent cause of diagnostic error. If these data are lacking, the stroke profile may still be determined by extending the period of observation for a few days or weeks, thus invoking the clinical rule that the physician's best diagnostic tool is a second and third examination.

There are few categories of neurologic disease whose temporal profile mimics that of the cerebrovascular disorders. Migraine may do so (see page 184), but the history usually provides the diagnosis. A seizure may be followed by a prolonged focal deficit (Todd's paralysis) but is rarely the initial event in a stroke; the setting in which these symptoms occur and their subsequent course clarify the clinical situation. Stroke-like episodes appear in the course of certain hereditary metabolic disorders (Fabry disease, homocystinuria, mitochondrial disease). Differentiation is not difficult because of the associated myopathic and neurologic signs and characteristic metabolic defects. Tumor, infection, inflammation, degeneration, and nutritional deficiency are not likely to manifest themselves precipitously, although rarely a brain metastasis produces a focal deficit of abrupt onset (see below). Trauma, of course, occurs abruptly but usually offers no problem in diagnosis. In multiple sclerosis and other demyelinating diseases, there may be an abrupt onset or exacerbation of symptoms, but for the most part they occur in a different age group and clinical setting. Conversely, a stroke-like onset of cerebral symptoms in a young adult should always raise a suspicion of demyelinating disease. A stroke developing over a period of several days usually progresses in a stepwise fashion, increments of deficit being added abruptly from time to time. A slow, gradual,

downhill course over a period of 2 weeks or more indicates that the lesion is probably not vascular but rather neoplastic, demyelinative, infectious (abscess) or granulomatous, or a subdural hematoma.

In regard to the *focal neurologic deficits* of cerebrovascular disease, many of the nonvascular diseases may produce symptoms that are much the same, and the diagnosis cannot rest solely on this aspect of the clinical picture. Nonetheless, certain combinations of neurologic signs, if they conform to a neurovascular pattern—e.g., the lateral medullary syndrome—confidently mark the disease as vascular- occlusive in nature.

Many thrombotic strokes are preceded by TIAs, which, if recognized, are diagnostic of this form of vascular disease. It is essential that TIAs be differentiated from seizures, syncope, panic attacks, neurologic migraine, and attacks of labyrinthine vertigo, since a failure to do so may result in unnecessary arteriographic studies and even a surgical operation.

With very few exceptions, the presence of *blood in the CSF* points to a cerebrovascular (rarely spinal vascular) lesion provided that trauma and a *traumatic* tap can be excluded. *Headache* is common in cerebrovascular disease; it occurs not only with hemorrhage but also with thrombosis, arterial dissections, and rarely with embolism. Seizures are almost never the premonitory, first, or only manifestation of a stroke but can occur in the first few hours after infarction or intracranial bleeding. *Brief unconsciousness* (5 to 10 min) is rare in stroke, being seen only with basilar artery insufficiency and as an initial event in ruptured aneurysm or primary intracerebral hemorrhage. In the latter case, a depression in the state of consciousness soon reasserts itself and is then progressive. Certain neurologic disturbances are hardly ever attributable to stroke—e.g., diabetes insipidus, fever, bitemporal hemianopia, parkinsonism, generalized myoclonus, and isolated cranial nerve palsies—and their presence may be of help in excluding vascular disease.

Finally, the diagnosis of cerebrovascular disease should always be made on positive data, not by exclusion.

A few conditions are so often confused with cerebrovascular diseases that they merit further consideration. When a history of trauma is absent, the headache, drowsiness, mild confusion, and hemiparesis of subdural hematoma may be ascribed to a “small stroke,” and the patient may fail to receive immediate surgical therapy. In subdural hematoma, the symptoms and signs usually develop gradually over a period of days or weeks. The degree of headache, obtundation, and confusion is disproportionately greater than the focal neurologic deficit, which tends to be indefinite and variable until late in the evolution of the hematoma. The CSF may be blood-tinged or xanthochromic when the type of stroke under suspicion would not be expected to show this. If the patient has fallen and injured his head at the onset of the stroke, it may be impossible to rule out a complicating subdural hematoma on clinical grounds alone, in which case CT scanning and MRI are usually diagnostic.

The reverse diagnostic error will not be made if one remembers that patients with subdural hematoma rarely exhibit a total hemiplegia, monoplegia, hemianesthesia, homonymous hemianopia, or aphasia. If such focal signs are present and particularly if they developed suddenly, subdural hematoma is not likely to be the explanation.

A brain tumor, especially a rapidly growing glioblastoma multiforme or lymphoma, may produce a severe hemiplegia within a week or two. Also, the neurologic deficit due to metastatic carcinoma may evolve rapidly. Moreover, in rare cases, the hemiplegia may be preceded by transitory episodes of neurologic deficit, indistinguishable from TIAs. In such cases, a tumor could be mistaken for a stroke. However, in both conditions, a detailed history will indicate that the evolution of symptoms was gradual; if it was saltatory, seizures will usually have occurred. A number of standard ancillary examinations should never be omitted in these circumstances. A chest film frequently discloses a primary or secondary tumor, and an increased blood sedimentation rate suggests that a concealed systemic disease process is at work. A lack of detailed history may also be responsible for the opposite diagnostic error, i.e., mistaking a relatively slowly evolving stroke (usually due to internal carotid artery or basilar occlusion) for a tumor. Again, CT scanning and MRI will usually settle the problem. A brain abscess or inflammatory necrotic lesion, e.g., toxoplasmosis, may develop without an evident focus of infection and may escape consideration, especially if the patient is elderly.

Senile dementia of the Alzheimer type is often ascribed, on insufficient grounds, to the occurrence of multiple small strokes. If vascular lesions are responsible, evidence of an apoplectic episode or episodes and of focal neurologic deficit to account for at least part of the syndrome will almost invariably be disclosed by history and examination. In the absence of a history of episodic development or of focal neurologic signs, it is unwarranted to attribute senile dementia to cerebrovascular disease—in particular to small strokes in silent areas. *Cerebral arteriosclerosis* is another term that has often been used carelessly to explain such mental changes, the implication (incorrect) being that arteriosclerosis itself causes ischemic damage to the nervous system, producing loss of intellectual function but no other neurologic signs. If cerebral arteriosclerosis (atherosclerosis) is actually responsible, there should be evidence of it in the form of strokes at some time in the course of the illness and often in the heart (myocardial infarction, angina pectoris) or legs (intermittent claudication, loss of pulses). Frequently the lesions of both vascular and Alzheimer disease are present, in which case there may be difficulty in determining to what extent each of them is responsible for the neurologic deficit.

Recurrent seizures as the result of stroke occur in some 10 to 20 percent of cases (*postinfarction epilepsy*). When evidence, by history or examination, of the original stroke is lacking, as it often is, or if the seizures are not observed or leave behind a temporary increase in the neurologic deficit (Todd's paralysis), the diagnosis of another stroke or a tumor may be made in error.

Fear, anxiety, and depression in patients who have had one stroke may lead to additional symptoms—such as generalized weakness, paresthesias, headache, impaired memory, or disequilibrium—and suggest to the patient and physician that further vascular lesions have occurred or threaten.

Miscellaneous conditions occasionally taken to be a stroke are Bell's palsy; Stokes-Adams attacks; a severe attack of labyrinthine vertigo; diabetic ophthalmoplegia; acute ulnar, radial, or peroneal palsy; embolism to a limb; and temporal arteritis associated with blindness.

Contrariwise, certain manifestations of stroke may be incorrectly interpreted as manifestations of some other neurologic disorder. In lateral medullary infarction, *dysphagia* may be the outstanding feature; if the syndrome is not kept in mind, a fruitless radiologic search for a local esophageal or pharyngeal cause may be undertaken. Similarly, *facial pain or a burning sensation*, due to involvement of the trigeminal spinal nucleus, may be misattributed to sinus disease. *Headache*, at times severe, often occurs as a prodrome of a thrombotic stroke or subarachnoid hemorrhage; unless this is appreciated, a diagnosis of migraine may be made. *Dizzy spells or brief intermittent* lapses of equilibrium due to vascular disease of the brainstem may be ascribed to vestibular neuronitis, Ménière disease, Stokes-Adams syncope, or paroxysmal tachycardia. A detailed account of the attack will usually avert this error. A strikingly focal monoplegia of cerebral origin, causing only weakness of the hand or arm or foot drop, is not infrequently misdiagnosed as a peripheral neuropathy.

In the presence of coma, the differentiation of vascular from other neurologic diseases offers special problems. If the patient is comatose when first seen and an adequate history is not available, cerebrovascular lesions have to be differentiated from all the other causes of coma described in [Chap. 17](#). Among cerebrovascular diseases, cerebral or subarachnoid hemorrhage and basilar artery occlusion are usually responsible. In most cases there will be some historical data and focal or lateralizing neurologic signs to direct the series of necessary diagnostic deductions; ancillary examinations, particularly CT scanning and MRI, assume special importance.

COMMON CLINICAL PROBLEMS IN Cerebrovascular disease

Inevitably, most patients are seen first by clinicians who may not be expert in all the fine points of cerebrovascular disease. Situations arise in which critical decisions must be made regarding anticoagulation, further laboratory investigation, and the advice and prognosis given to the family. The following are some of the situations which the authors have encountered that may be of value to students and residents and to nonspecialists in the field.

The patient with a history of an ischemic attack or small stroke in the past The patient may be functioning normally when examined, but it has been ascertained by the history or radiologic procedures that a stroke or TIA occurred in the past. The problem is what measures should be taken to reduce the risk of further strokes. This is particularly problematic if a surgical procedure is planned. A brief focal TIA, several minutes or less in duration, or many stereotyped spells usually represent severe stenosis of the internal carotid artery on the side of the affected cerebral hemisphere. If the symptoms have occurred recently, these may be forerunners of complete occlusion. If the TIA was distant in the past—more than several weeks previously—the immediate risks of occlusion are reduced. The initial approach is to establish the patency of the carotid arteries by ultrasound or MRA. If there is a reduction in diameter of greater than 70 percent when compared with an adjacent normal segment of vessel, and probably if there is a severely ulcerated but not critically stenotic plaque, carotid surgery (or angioplasty) is advisable. If a single TIA lasted more than an hour or the neurologic examination discloses minor signs referable to the region of the hemisphere affected by the TIA, a search for a source of embolus is indicated. Appropriate diagnostic studies include ECG, a transesophageal echocardiogram, monitoring for cardiac arrhythmia, ultrasound of the carotid arteries, and a CT scan or MRI if it has not already been performed. Preventive anticoagulation (warfarin) is instituted if a source of clot within the cardiac chambers is

found or if there is atrial fibrillation. Aspirin is appropriate but not imperative if no abnormality is found. Control of elevated blood pressure and perhaps addressing high cholesterol levels are ancillary steps. The mistake is to ignore the potential significance of a small stroke.

Patients with a recent stroke that may not be complete Here the basic problem is whether a thrombotic infarction (venous or arterial) will spread and involve more brain tissue, or if embolic, whether the ischemic tissue will become hemorrhagic or another embolus will occur, or if there is an arterial dissection, whether it will give rise to emboli. Therapies are controversial in most of these circumstances. In some centers it is the practice to try to prevent propagation of a thrombus by administering heparin (or low-molecular-weight heparin) followed by warfarin, as discussed earlier. Thrombolytic agents are an alternative if the stroke has occurred within the previous 2 or 3 h and is not too large. Except perhaps in cases of recent myocardial infarction, atrial fibrillation, or carotid disease, it is not imperative to begin heparin immediately while awaiting the effects of warfarin.

The inevident or misconstrued syndromes of cerebrovascular disease Although hemiplegia is the classic type of stroke, cerebrovascular disease may manifest itself by signs that spare the motor pathways but have the same serious diagnostic and therapeutic implications. The following stroke syndromes tend to be overlooked.

Sometimes disregarded is a leaking aneurysm presenting as a sudden and intense generalized headache lasting hours or days and unlike any headache in the past. Examination may disclose no abnormality except for a slight stiff neck and raised blood pressure. Failure to investigate such a case by imaging procedures and examination of the CSF may permit the occurrence of a later massive subarachnoid hemorrhage. Small cerebral hemorrhages, subdural hematomas, or brain tumors figure into the differential diagnosis, which is usually settled by a CT scan or MRI.

A second inobvious stroke is one caused by occlusion of the posterior cerebral artery, usually embolic. This may not be recognized unless the visual fields are routinely tested at the bedside. The patient himself may not be aware of the difficulty or will complain only of blurring of vision or the need for new glasses. Accompanying deficits are inability to name colors or recognize manipulable objects or faces, difficulty in reading, etc. MRI or CT scanning usually corroborates the clinical diagnosis, and therapy is directed against further emboli or extension of the thrombosis.

Another inapparent or confounding stroke that may be mistaken for psychiatric disease is an attack of paraphasic speech from embolic occlusion of a branch of the left middle cerebral artery. The patient talks in nonsensical phrases, appears confused, and does not fully comprehend what is said to him. He may perform satisfactorily at a superficial level and make socially appropriate greetings and gestures. Only scrutiny of language function and behavior will lead to the correct diagnosis. Infarction (or trauma) of the dominant or nondominant temporal lobe and rarely of the caudate may produce an agitated delirium with few focal findings. This may be mistaken for a toxic or withdrawal state.

Parietal infarctions on either side (usually nondominant hemisphere) are often missed because the patient is entirely unaware of the problem or the symptoms create only a subtle confusional state, drowsiness, or only subtle problems with calculation, dialing a phone, reaching accurately for objects, or loss of ability to write. Extinction of bilaterally presented visual or tactile stimuli gives a clue; marked asymmetry of the optokinetic nystagmus response is sometimes the only definite sign.

A cerebellar hemorrhage may at first be difficult to recognize as a stroke. An occipital headache and complaint of dizziness with vomiting may be interpreted as a labyrinthine disorder, gastroenteritis, or myocardial infarction. A slight ataxia of the limbs, inability to stand, and mild gaze paresis may not have been properly tested or have been overlooked. Early intervention by surgery may be lifesaving; but once the syndrome has progressed to the point of coma and pupillary abnormalities with bilateral Babinski signs, surgery is most often useless.

Periventricular white matter changes (leukoareosis) correlate poorly with cerebrovascular disease and we prefer to ignore them.

The comatose stroke patient The most common causes of vascular coma are intracranial hemorrhage—usually deep in the hemisphere, less often in the cerebellum or brainstem, extensive subarachnoid hemorrhage, and basilar artery occlusion. After several days, brain edema surrounding a large infarction in the territory of the middle cerebral artery or adjacent to a hemorrhage may produce the same effect. Certain remedial surgical measures are still available in these circumstances: drainage of blood from the ventricles, shunting of the ventricles in cases of secondary hydrocephalus due to obstruction of the third ventricle or aqueduct, evacuation of a cerebral hemorrhage in cases of recent decline into stupor and coma, and hemicraniectomy in the case of massive stroke edema. Also, thrombolytic therapy and anticoagulants are sometimes successful in reversing the progression of basilar artery thrombosis. These procedures are best carried out in centers with experience in cerebrovascular intensive care. If coma persists or is deep and sudden, only supportive treatment is possible.

Chapter 35

CRANIOCEREBRAL TRAUMA

Definitions and Mechanisms

Basal Skull Fractures and Cranial Nerve Injuries

Carotid-Cavernous Fistula

Pneumocephalus, Aerocele, and Rhinorrhea (Cerebrospinal Fluid Leak)

Cerebral Concussion

Pathologic Changes Associated with Severe Head Injury

Approach to the Patient with Head Injury

Patients who are Conscious or are Rapidly Regaining Consciousness (Minor Head Injury)

Patients who Have Been Comatose from the Time of Head Injury

Concussion Followed by a Lucid Interval and Serious Cerebral Damage

Penetrating Wounds of the Head

Sequelae of Head Injury

Other Posttraumatic Cognitive and Psychiatric Disorders

Treatment

Patients with only Transient Unconsciousness

Severe Head Injury

Prognosis

Chapter References

Among the vast array of neurologic diseases, cerebral trauma ranks high in order of frequency and gravity. In the United States, in persons up to 44 years of age, trauma is the leading cause of death, and more than half of these deaths are due to head injuries. Each year, according to the American Trauma Society, an estimated 500,000 Americans are admitted to hospitals following cerebral trauma; of these, 75,000 to 90,000 die and even larger numbers, most of them young and otherwise healthy, are left permanently disabled.

The basic problem in craniocerebral trauma is at once both simple and complex: simple because there is usually no difficulty in determining causation—namely, a blow to the head—complex because of a number of delayed effects that may complicate the injury. As for the trauma itself, nothing medical can be done, for it is finished before the physician arrives on the scene. At most there can be an assessment of the full extent of the immediate cerebral injury, an evaluation of factors conducive to complications and further lesions, and the institution of measures to avoid such additional problems. But of the disastrous intracranial phenomena that can be initiated by head injury, several fall within the purview of the neurologist, for they are secondary effects that evolve during the period of medical observation, offering possibilities of treatment.

It is a common misconception that craniocerebral injuries are matters that concern only the neurosurgeon and not the general physician or neurologist. Actually, some 80 percent of head injuries are first seen by a general physician in an emergency department, and probably fewer than 20 percent ever require neurosurgical intervention of any kind—even this number is decreasing. Often neurologists must take charge of the head-injured patient, or their opinion is sought in consultation. To enact their role effectively, they must be familiar with the clinical manifestations and the natural course of the primary brain injury and its complications and have a sound grasp of the underlying physiologic mechanisms. Such knowledge must be up to date and immediately applicable, particularly as it relates to the interpretation of computed tomography (CT) scans and magnetic resonance imaging (MRI), both of which have greatly enhanced our ability to deal with head trauma and its complications. The present chapter reviews the salient facts concerning craniocerebral injuries and outlines a clinical approach that the authors have found useful over the years. Matters pertaining to spinal injury are considered in [Chap. 44](#).

DEFINITIONS AND MECHANISMS

The very language that one uses to discuss certain types of head injury divulges a number of misconceptions inherited from previous generations of physicians. Certain words have crept into the medical vocabulary and have often been retained long after the ideas for which they stood have been refuted—attesting to the disadvantage of premature adoption of explanatory terms rather than descriptive ones. The word *concussion*, for example, implies a violent shaking or jarring of the brain and a resulting transient functional impairment. Yet despite numerous postulates of physical changes within nerve cells, axons, or myelin sheaths (vibration effects, formation of intracellular vacuoles, etc.), little convincing confirmation of their existence has been possible in humans or in experimental animals. Similarly the word *contusion*, meaning a bruising of cerebral tissue without interruption of its architecture, is applied rather indiscriminately to a variety of clinical states, some of which could not depend on a pathologic change of this type, e.g., “minor contusion state or syndrome”—an expression introduced by Wilfred Trotter, who was himself most critical of words that “embalm a fallacious theory.”

In all attempts to analyze the mechanisms of *closed*, or *blunt (nonpenetrating)*, head injury, one fact stands pre-eminent—that there must be the sudden application of a physical force of considerable magni-tude to the head. Unless the head is struck, the brain suffers no injury—except in the rare instances of violent flexion-extension (whiplash) of the neck and somewhat controversial cases of crush injury to the chest or explosive injury with a sudden extreme increase of intrapulmonary pressure. The factors of particular importance in brain injury are the differential mobility of the head and brain, the tethering of the cerebral hemispheres at the upper brainstem, and the differing densities of the gray and white matter. As pointed out below, all concussive injuries involve a physical force that imparts motion to the stationary head or a hard surface that arrests the motion of the moving head. This is the basis of most civilian head injuries, and they are notable in two respects: (1) they frequently induce at least a temporary loss of consciousness and (2) even though the skull is not penetrated, the brain may suffer gross damage, i.e., contusion, laceration, hemorrhage, and swelling. A theory that would bring into plausible form these gross neuropathologic changes and the transient loss of consciousness (concussion) or prolonged coma has been formulated only in relatively recent years.

By contrast, high-velocity missiles may penetrate the skull and cranial cavity or, rarely, the skull may be compressed between two converging forces that crush the brain without causing significant displacement of the head or the brain. In these circumstances the patient may suffer severe and even fatal injury without immediate loss of consciousness. Hemorrhage, destruction of brain tissue, and, if the patient survives for a time, meningitis or abscess are the principal pathologic changes created by injuries of these types. They offer little difficulty to our understanding. These various types of head injuries are illustrated in [Fig. 35-1](#).

Figure 35-1 Mechanisms of craniocerebral injury. A. Cranium distorted by forceps (birth injury). B. Gunshot wound of the brain. C. Falls (also traffic accidents). D. Blows on the chin (“punch drunk”). E. Injury to skull and brain by falling objects. [From [Courville](#) (a study based upon a survey of lesions found in a series of 15,000 autopsies). By permission.]

The relation of *skull fracture* to brain injury has been viewed in changing perspective throughout the history of this subject. In the first half of the century, fractures dominated the thinking of the medical profession, and cerebral lesions were regarded as secondary. Later, it became known that the skull, though rigid, is still flexible enough to yield to a blow that could injure the brain without causing fracture. Therefore, the presence of a fracture, although a rough measure of the force to which the brain has been exposed, is no longer considered an infallible index of the presence of cerebral injury. Even in fatal head injuries, autopsy reveals an intact skull in some 20 to 30 percent of cases (see also page 933). Contrariwise, many patients suffer skull fractures without serious or prolonged disorder of cerebral function, in part because the energy of a blow is dissipated in the fracture.

The modern trend is to be concerned primarily with the presence or absence of brain injury rather than with the fracture of the skull itself. Nevertheless, fractures cannot be dismissed without further comment for several reasons. The presence of a fracture always warns of the possibility of cerebral injury. Overall, brain injury is estimated to be 5 to 10 times more frequent with skull fracture than without and perhaps 20 times more frequent with severe injuries. Moreover, fractures assume importance in indicating the site and possible severity of brain damage, in providing an explanation for cranial nerve palsies, and in creating potential pathways for the ingress of bacteria and air or the egress of cerebrospinal fluid (CSF). In all these respects, fractures through the base of the skull are of special significance (more so than those of the cranial vault) and are considered below.

Basal Skull Fractures and Cranial Nerve Injuries

Some of the major sites and directions of basilar skull fractures are indicated in [Fig. 35-2](#). One can readily perceive the possibilities of injury to cranial nerves in relation to such fractures. Fractures of the base are often difficult to detect in plain skull films, but their presence should always be suspected if any one of a number of characteristic clinical signs is in evidence. Fracture of the petrous pyramid often deforms the external auditory canal or tears the tympanic membrane, with leakage of CSF (otorrhea); or, blood may collect behind an intact tympanic membrane and discolor it. If the fracture extends more posteriorly, damaging the sigmoid sinus, the tissue behind the ear and over the mastoid process becomes boggy and discolored (Battle sign). Basal fracture of the anterior skull may cause blood to leak into the periorbital tissues, imparting a characteristic “raccoon” or “panda bear” appearance. The presence of any of these signs calls for CT scanning of the skull base using bone window settings.

Figure 35-2 The course of fracture lines through the base of the skull. Arrows indicate point of application and direction of force. (From [Courville](#) by permission.)

Commonly the existence of a basal fracture is indicated by signs of cranial nerve damage. The olfactory, facial, and auditory nerves are the ones most liable to injury, but any one, including the twelfth, may be damaged. *Anosmia and an apparent loss of taste* (actually a loss of perception of aromatic flavors, since the elementary modalities of taste—salt, sweet, bitter, sour—are unimpaired) are frequent sequelae of head injury, especially with falls on the back of the head. In the majority of cases the anosmia is permanent. If unilateral, it will not be noticed by the patient. The mechanism of these disturbances is thought to be a displacement of the brain and tearing of the olfactory nerve filaments in or near the cribriform plate, through which they course.

A fracture in or near the sella may tear the stalk of the pituitary gland, with resulting *diabetes insipidus*, impotence and reduced libido, and amenorrhea. Rarely such a fracture may cause bleeding from a pre-existing pituitary adenoma and produce the syndrome of pituitary apoplexy (page 717). A fracture of the sphenoid bone may lacerate the optic nerve, with blindness from the beginning. The pupil is unreactive to a direct light stimulus but still reacts to a light stimulus to the opposite eye (consensual reflex). The optic disc becomes pale, i.e., atrophic, after an interval of several weeks. Partial injuries of the optic nerve may result in scotomas and a troublesome blurring of vision.

Complete *oculomotor nerve injury* is characterized by ptosis, a divergence of the globes with the affected eye resting in an abducted and elevated position, loss of medial and vertical movements of the eye, and a fixed, dilated pupil. Diplopia—worse on looking down—and compensatory tilting of the head suggest *trochlear nerve* injury. In a series of 60 patients with recent head injury, Lepore found that fourth nerve palsy was the commonest cause of diplopia, occurring unilaterally twice as often as bilaterally, followed in frequency by damage to one or both third nerves, then, least frequently, to the sixth nerves. Five of his patients had palsies that reflected damage to more than one nerve, and seven had supranuclear disorders of convergence. These optic and ocular motor nerve disorders must be distinguished from those due to displacement of the globe by direct injury to the orbit and the oculomotor muscles.

Injury to the *ophthalmic and maxillary divisions of the trigeminal nerve* may be the result of either a basal fracture across the middle cranial fossa or a direct extracranial injury to the branches of the nerves. Numbness and paresthesias of the skin supplied by the nerve(s) or a neuralgia can be troublesome sequelae of these injuries.

The *facial nerve* may be involved in one of two ways. In one, associated with transverse fractures through the petrous bone, there is an immediate facial palsy, probably due to transection of the nerve. Surgical anastomosis has sometimes been successful in this circumstance. In the second, more common type, associated with longitudinal fractures of the petrous bone, the facial palsy is delayed for several days—a sequence that may be misinterpreted as progression of the intracranial traumatic lesion. The second type is usually transitory, and its mechanism is not known.

Injury to the *eighth cranial nerve*, due to petrous fractures, results in a loss of hearing or in postural vertigo and nystagmus coming on immediately after the trauma. Deafness due to nerve injury must be distinguished from the high-tone hearing loss due to *cochlear* injury and from deafness caused by bleeding into the middle ear, with disruption of the ossicular chain (conduction deafness). Also, vertigo must be distinguished from posttraumatic giddiness. A fracture through the hypoglossal canal causes weakness of one side of the tongue. It should be kept in mind that blows to the upper neck may also cause lower cranial nerve palsies, either by direct injury to their peripheral extensions or as a result of *carotid artery dissection*, either of its cervical or intracranial segment.

Carotid-Cavernous Fistula

A basal fracture through the sphenoid bone may lacerate the internal carotid artery or one of its intracavernous branches, where it lies in the cavernous sinus. Within hours or a day or two, a disfiguring pulsating exophthalmos develops as arterial blood enters and distends the superior and inferior ophthalmic veins that empty into the sinus. The orbit feels tight and painful, and the eye may become partially or completely immobile because of pressure on the oculomotor nerves, which traverse the sinus ([Fig. 14-3](#)). The sixth nerve is affected most often and the third and fourth nerves less frequently. Also, there may be a loss of vision, due to ischemia of the optic nerve and retina; congestion of the retinal veins and glaucoma are additional factors in the visual failure. Some 5 to 10 percent of fistulas resolve spontaneously, but the remainder must be obliterated by interventional radiologic means (by a detachable balloon inserted via a catheter transfemorally) or by a direct surgical repair of the fistula (Stern).

Not all carotid-cavernous fistulas are traumatic. They may occasionally occur with rupture of an intracavernous saccular aneurysm or in Ehlers-Danlos disease, where the connective tissue is defective; or the cause may be unexplained.

Pneumocephalus, Aerocele, and Rhinorrhea (Cerebrospinal Fluid Leak)

If the skin over a skull fracture is lacerated and the underlying meninges are torn, or if the fracture passes through the inner wall of a paranasal sinus, bacteria may enter the cranial cavity, with resulting meningitis or abscess. Also, CSF may leak into the sinus and present as a watery discharge from the nose (*CSF rhinorrhea*). The nasal discharge can be identified as CSF by testing it for glucose with diabetic test tape (mucus has no glucose) or for the presence of fluorescein or iodinated water-soluble dye that is injected into the lumbar subarachnoid space and then absorbed by pledgets placed in the nasal cavity. Most cases of acute CSF rhinorrhea heal by themselves. If the condition is persistent or is complicated by an episode of meningitis, repair of the torn dura mater is indicated. The prophylactic use of antibiotics to prevent meningitis from a CSF leak is not favored, but many neurosurgeons continue this practice, particularly in children (see page 743).

A collection of air in the cranial cavity (aerocele) is a common occurrence following skull fracture or an extended neurosurgical procedure. It is usually found (by CT scan) in the epidural or subdural space over the convexities or between the hemispheres and serves only to warn of a potential route for the entry of bacteria into the cranium. Small collections of air are usually absorbed without incident, but a large collection of air may act as a mass and cause clinical deterioration after injury (tension pneumocranium; [Fig. 35-3](#)). Inhalation of 100% oxygen has a transient salutary effect, but needle aspiration of the air is required if it is causing clinical signs ([Fig. 35-3](#)).

Figure 35-3 CT of postoperative tension pneumocranium (aerocele) that caused progressive drowsiness and required removal by aspiration. The air is apparent as a very low density collection that compresses the frontal lobes.

Depressed (“derby hat”) fractures are of significance only if the underlying dura is lacerated or the brain is compressed by indentation of bone. They should then be surgically repaired, preferably within the first 24 to 48 h.

Cerebral Concussion

Mechanisms of Concussion Much has been written about the mechanisms of concussion and coma in closed, or blunt, head injury. Certain facts concerning these conditions stand out: (1) Concussion, meaning a *reversible traumatic paralysis of nervous function*, is always immediate (not delayed even by seconds). (2) The effects of concussion on brain function may last for a variable time (seconds, minutes, hours, or longer). To set arbitrary limits on the duration of loss of consciousness—i.e., to consider a brief loss as indicative of concussion and a prolonged loss as indicative of contusion or other traumatic cerebral lesion, as proposed in some medical writings—is illogical and unsound physiologically. As pointed out by Symonds, any such difference is quantitative, not qualitative. Admittedly, in the more prolonged states of coma, there is a greater chance of finding hemorrhage and contusion, which undoubtedly contribute to the persistence of coma and the likelihood of irreversible change. (3) The optimal condition for the production of concussion, demonstrated originally by Denny-Brown and Russell, is a change in the momentum of the head; i.e., either movement is imparted to the head by a blow or movement of the head is arrested by a hard, unyielding surface. These two types of blunt (nonpenetrating) head injury are called *accelerative* and *decelerative*, respectively.

The mechanism of concussive cerebral paralysis has been interpreted in various ways throughout medical history in light of the state of scientific knowledge at a particular time. The favored hypotheses for the better part of a century were “vasoparalysis” (suggested by Fischer in 1870) or an arrest of circulation by an instantaneous rise in intracranial pressure (proposed by Strohmeyer in 1864 and popularized by [Trotter in 1932](#)). Jefferson, in his essay on the nature of concussion (1944), convincingly refuted these vascular hypotheses; later, Shatsky and coworkers, by the use of high-speed cineangiography, showed displacement of vessels but no arrest of circulation immediately after impact.

Beginning with the work of Denny-Brown and Russell in 1941, the physical factors involved in head and brain injury have been subjected to careful analysis. These investigators demonstrated, in the monkey and cat, that concussion resulted when the freely moving head was struck by a heavy mass. If the head was prevented from moving at the moment of impact, the same degree of force invariably failed to produce concussion. More recently, the importance of head motion per se was verified by Gennarelli and colleagues, who were able to induce concussion in primates by rapid acceleration of the head without impact, a condition that rarely occurs in humans.

Holbourn (1943), a Cambridge physicist, from a study of gelatin models under conditions simulating head trauma, deduced that when the head is struck, movement of the partly tethered but suspended brain always lags (inertia); but inevitably the brain moves also, and when it does it must rotate, for it occupies a round skull whose motions (because of attachment to the neck) usually describe an arc. Pudenz and Sheldon and later Ommaya and coworkers (1974) proved the correctness of this assumption by photographing the brain through a transparent (Lucite) calvarium at the moment of impact. The brain is thus subjected to shearing stresses set up by rotational forces centered at its point of tethering in the high midbrain and subthalamus. The torque at the level of the upper reticular formation would explain the immediate loss of consciousness, as described below. Also, these rotational movements of the brain provide a reasonable explanation for the occurrence of surface injuries in certain places, i.e., where the swirling brain comes into contact with bony prominences on the inner surface of the skull (petrous and orbital ridges, sphenoid wings), and of injuries to the corpus callosum, which is flung against the falx.

These views on the site and mechanism of concussion were supported by a number of additional observations. Foltz and Schmidt, in 1956, suggested that the reticular formation of the upper brainstem was the anatomic site of concussive injury. They showed that in the concussed monkey, lemniscal sensory transmission through the brainstem was unaltered but its effect in activating the high reticular formation was blocked. They also demonstrated that the electrical activity of the medial reticular formation was depressed for a longer time and more severely than that of the cerebral cortex.

In 1956 and again in 1961, Strich described the neuropathologic findings in patients who died months after severe closed head injuries that had caused immediate and protracted coma. In all of her cases—in which there were no signs of skull fracture, raised intracranial pressure, or gross subarachnoid hemorrhage—she observed an uneven but diffuse degeneration of the cerebral white matter. In cases of shorter survival (up to 6 weeks), she observed ballooning and interruption of axis cylinders. These findings were subsequently confirmed by Nevin, by J. H. Adams and colleagues, and by Gennarelli et al, the last of these groups working with monkeys. It is noteworthy that in most of these cases and subsequent ones reported by Jellinger and Seitelberger, there were also lesions in the region of the reticular activating system and small hemorrhagic softenings in the corpus callosum, superior cerebellar peduncles, and dorsolateral tegmentum of the midbrain. Strich interpreted the extensive white matter lesions, both in the hemispheres and in the brainstem, to represent a primary degeneration of nerve fibers that had been stretched or torn by the shear stresses set up during rotational acceleration of the head (*diffuse axonal injury*), as had been postulated earlier by Holbourn. She suggested that if nerve fibers are stretched rather than torn, the lesions may be reversible and may play a part in the production of concussion. Symonds elaborated this view. He saw in the shearing stresses—which are maximal at the point where the cerebral hemispheres rotate on the relatively fixed brainstem (i.e., at the midbrain-subthalamic level)—the explanation of concussion.

Clinical Manifestations of Concussion The immediate abolition of consciousness, suppression of reflexes (falling to the ground if standing), transient arrest of respiration, a brief period of bradycardia, and fall in blood pressure following a momentary rise at the time of impact are the characteristic clinical signs of concussive injury. Rarely, if these abnormalities are sufficiently intense, death may occur at this moment, presumably from respiratory arrest. Usually the vital signs return to normal and stabilize within a few seconds while the patient remains unconscious. The plantar reflexes are extensor. Then, after a variable period of time, the patient begins to stir and opens his eyes but is unseeing. Corneal, pharyngeal, and cutaneous reflexes, originally depressed, return, and the limbs are withdrawn from painful stimuli. Gradually contact is made with the environment, and the patient begins to obey simple commands and respond slowly and inadequately to simple questions.

Memories are not formed during this period; the patient may even carry on a conversation which, later on, he cannot recall. Finally there is full recovery, corresponding to the time when the patient can form consecutive memories of current experiences. The time required for the patient to pass through these stages of recovery may be only a few seconds or minutes, several hours, or possibly days; but again, between these extremes there are only quantitative differences, varying with the intensity of the process. To the observer, such patients are comatose only from the moment of injury until they open their eyes and begin to speak; for the patient, the period of unconsciousness extends from a point before the injury occurred (*retrograde amnesia*) until the time when he is able to form consecutive memories—namely, at the end of the period of anterograde amnesia. The duration of the amnesic period, particularly of *anterograde amnesia*, is the most reliable index of the severity of the concussive injury. If there is no disturbance or loss of consciousness, none of the lesions described below are to be found.

Pathologic Changes Associated with Severe Head Injury

In fatal cases of head injury, the brain is often bruised, swollen, and lacerated and there may be hemorrhages, either meningeal or intracerebral, and hypoxic-ischemic lesions. The prominence of these pathologic findings were responsible for the long-prevailing view that cerebral injuries are largely a matter of bruises (*contusions*), hemorrhages, and the need for urgent operations. That this can hardly be the case is indicated by the fact that some patients survive and make an excellent recovery from head injuries that are clinically as severe or almost as severe as the fatal ones. One can only conclude, therefore, that most of the immediate symptoms of severe head injury depend on invisible and highly reversible changes, i.e., the changes underlying concussion.

The effects of bruises, lacerations, hemorrhages, localized swellings, white matter necroses, and herniations of tissue should not be minimized, since they are probably responsible for or contribute to many of the fatalities that occur 12 to 72 h or more after the injury. As pointed out by Jennett, a majority of patients who remain in coma for more than 24 h after a head injury are found to have intracerebral hematomas. Of these lesions, the most important are contusions of the surface of the brain beneath the point of impact (*coup lesion*) and the more extensive lacerations and contusions on the side opposite the site of impact (*contrecoup lesion*) as shown in [Fig. 35-4](#). Blows to the front of the head produce mainly coup lesions, whereas blows to the back of the head cause mainly contrecoup lesions (sometimes coup lesions as well). Blows to the side of the head produce either coup or contrecoup lesions or both. Irrespective of the site of the impact, the common sites of cerebral contusions are in the frontal and temporal lobes, as illustrated in [Fig. 34-4](#) and [Fig. 35-5](#). The inertia of the malleable brain—which causes it to be flung against the side of the skull that was struck, to be pulled away from the contralateral side, and to rotate against bony prominences within the cranial cavity—explains these coup-contrecoup contusions. As noted, the experimental studies of Ommaya and others indicate that the effects of linear acceleration of the head are much less significant than those due to rotation. Relative sparing of the occipital lobes in coup-contrecoup injury is explained by the smooth inner surface of the occipital bones and tentorium.

Figure 35-4 Mechanisms of cerebral contusion. Arrows indicate point of application and direction of force; black areas indicate location of contusion. A. Frontotemporal contusion consequent to frontal injury. B. Frontotemporal contusion following occipital injury. C. Contusion of temporal lobe due to contralateral injury. D. Frontotemporal contusion due to injury to opposite temporo-occipital region. E. Diffuse mesial temporo-occipital contusion due to blow on vertex. (From [Courville](#) by permission.)

Figure 35-5 CT scan without contrast infusion showing areas of hemorrhagic contusion adjacent to bony prominences.

The contused area of cortex is diffusely swollen and hemorrhagic, most of the blood being found around parenchymal vessels. On CT scanning, the contusions appear as edematous regions of cortex and subcortical white matter admixed with areas of increased density representing leaked blood ([Fig. 35-5](#)). The bleeding points may coalesce and give the appearance of a clot in the cortex and immediately subjacent white matter. The predilection of these lesions for the crowns of convolutions attests to their traumatic origin (being thrown against the overlying skull) and distinguishes them from cerebrovascular and other cerebral lesions.

In nearly all cases of severe head injury there is damage to the corpus callosum by impact with the falx; necrosis and hemorrhage are sometimes visible by CT scanning and can be seen to spread to adjacent white matter. Also, there may be scattered hemorrhages in the white matter along lines of force from the point of impact. Areas of white matter degeneration of the type described by Strich may also be present. In the authors' pathologic material, these white matter lesions tend to be focal, some in regions near hemorrhages, contusions, and ischemic lesions and others at a distance, along transcallosal and ascending and descending tracts that had been interrupted by such lesions. As indicated earlier, the degeneration of white matter can be remarkably diffuse, with no apparent relationship to focal destructive lesions. This *diffuse axonal injury*, as it is now generally designated, and the callosal and midbrain injuries are the predominant abnormalities in many cases of severe head injury. Recent investigations using MRI, such as the one by Kampfl and colleagues, indicate that diffuse injury of this type is a common substrate of the persistent vegetative state. They found a pattern of damage in the corpus callosum, corona radiata, and the dorsolateral midbrain tegmentum that conformed closely to pathologic changes in cases of diffuse axonal injury. But in all of our cases of severe cranial injury and protracted coma, there were zones of ischemia and old hemorrhages in the midbrain and subthalamus—i.e., in the zones subjected to the greatest torque—and we continue to favor these as the critical lesions in cases of persistent coma ([Ropper and Miller](#)). This was true also of the cases of persistent coma described by Jellinger and Seitelberger. It should be pointed out that in the aforementioned study by Kampfl there were MRI lesions in the thalamic region in only 40 percent of cases. Notable again is the fact that these deep lesions coincide with the postulated locus of reversible concussive paralysis.

Primary brainstem hemorrhages, as described above, are to be distinguished from the secondary so-called Duret hemorrhages resulting from the effects of downward and lateral displacement of the brainstem (transtentorial herniations). Duret originally emphasized the medullary location of these hemorrhages, but the term *Duret hemorrhage* has come to signify any secondary brainstem hemorrhage.

In addition to contusions and extradural, subdural, subarachnoid, and intracerebral hemorrhages, there are variable degrees of vasogenic edema, which increases in the first 24 to 48 h, and zones of infarction, apparently due to vascular spasm from subarachnoid blood surrounding basal vessels, similar to the situation that pertains in aneurysmal subarachnoid hemorrhage. Marmarou et al have convincingly demonstrated that *brain swelling* after head injury is essentially the result of edema and not of an increase in cerebral blood volume, as has long been postulated. In children and in some cases in adults, the cerebral edema may be massive and lead to

secondary brainstem compression (see page 941).

APPROACH TO THE PATIENT WITH HEAD INJURY

The physician first called upon to attend a patient who has had a closed (blunt) head injury will generally find the patient in one of three clinical conditions, each of which must be dealt with differently. Usually it is possible to categorize the patient in this way by assessing his mental and neurologic status when first seen and at intervals after the accident. In many emergency wards and intensive care units, the *Glasgow Coma Scale* is used as a rapid and effective means to accomplish this purpose ([Table 35-1](#)). The scores provided by this scale have been found to correspond roughly with outcome of the head injury, as discussed further on.

<i>Eyes open</i>	
Never	1
To pain	2
To verbal stimuli	3
Spontaneously	4
<i>Best verbal response</i>	
No response	1
Incomprehensible sounds	2
Inappropriate words	3
Disoriented and converses	4
Oriented and converses	5
<i>Best motor response</i>	
No response	1
Extension (decorticate rigidity)	2
Flexion abnormal (decorticate rigidity)	3
Flexion withdrawal	4
Localizes pain	5
Obeys	6
Total	3=15

Table 35-1 Glasgow Coma Scale (Total score is used for serial assessment and prognosis)

Patients Who Are Conscious or Are Rapidly Regaining Consciousness (Minor Head Injury)

This is the most frequently encountered clinical situation. Roughly, two degrees of disturbed function can be recognized within this category. In one, the patient was not unconscious at all but only stunned momentarily or “saw stars.” This injury is insignificant when judged in terms of life or death and brain damage—though, as we point out further on, there is always the possibility of a skull fracture or the later development of an epidural or subdural hematoma. Moreover, the patient is still liable to a troublesome posttraumatic syndrome—consisting of headache, giddiness, fatigability, insomnia, and nervousness—which may appear soon after or within a few days of the injury. In the second instance, consciousness was temporarily abolished for a few seconds or minutes, i.e., the patient was concussed. When such a patient is first seen, recovery may already be complete, or he may be in one of the stages of recovery described earlier under “Clinical Manifestations of Concussion.” Even though mentally clear, the patient may have an amnesia for events immediately preceding and following the injury. Thereafter, headache and other symptoms of the posttraumatic syndrome or compensation neurosis may develop.

In most cases of this type, there is little need of a neurologic consultation, and hospitalization is not required provided that a responsible family member is available to report any change in the clinical state. In only a small group of these patients, mainly in those who are slow in regaining consciousness or have a skull fracture, is there significant risk of ongoing hemorrhage or other delayed complications. Whether to obtain films of the head routinely in such patients is an unresolved problem. In our litigious society, the physician is inclined to do so. If there is no fracture and the patient is mentally clear, Jennett estimates that there is only one chance in a thousand of developing an intracranial (extradural) hemorrhage. He states that this increases to 1 in 30 in patients with a fracture; but most studies, such as the one by Lloyd and colleagues, have found that the presence of a skull fracture in children is a relatively poor indicator of intracranial injury.

These minor and seemingly trivial head injuries may sometimes be followed by a number of puzzling and worrisome clinical phenomena, some insignificant, others serious and indicative of a pathologic process other than concussion. The latter are described below. When they occur, a neurologic or neurosurgical evaluation is indicated.

Delayed Fainting after Head Injury Following an accident, the injured person, after walking about and seeming to be normal, may turn pale and fall unconscious to the ground. Recovery occurs within a few seconds or minutes. This is a vasodepressor syncopal attack, related to pain and emotional upset and differing in no way from the syncope that follows pain and fright without injury. Such syncopal attacks also occur with injuries that spare the head, but with head injury they become more difficult to interpret.

Denny-Brown described a more severe type of delayed posttraumatic collapse that we have seen only rarely. Again, the patient appears to be recovering from a blow to the head, which may simply have dazed him or caused a brief period of unconsciousness, when suddenly, after a period of several minutes to hours, he collapses and becomes unresponsive. The most disquieting feature of this clinical state is a marked bradycardia, which, coupled with the lucid interval, raises the specter of an evolving epidural hemorrhage (actually, bradycardia is a late and inconstant sign of epidural bleeding). However, intracranial pressure is not raised, the disorder fails to develop further, and—following a brief period of restlessness, vomiting, and headache—the patient recovers completely over a period of several days. Denny-Brown suggested that this form of delayed posttraumatic collapse was due to a contusion of the medulla, but how this explains the sequence of clinical events is not clear. The authors believe it to be a severe form of vasodepressor syncope.

A more serious form of delayed collapse after head injury is described further on under “Concussion Followed by a Lucid Interval.”

Drowsiness, Headache, and Confusion This syndrome occurs most often in children, who, after a concussive or nonconcussive head injury, seem not to be themselves. They lie down, are drowsy, complain of headache, and may vomit—symptoms that suggest the presence of an epidural or subdural hemorrhage. Mild focal edema near the point of impact may be seen on MRI. There is usually no skull fracture. The symptoms subside after a few hours, attesting to the benign nature of the condition.

Transient Traumatic Paraplegia, Blindness, and Migrainous Phenomena With falls or blows on top of the head, both legs may become temporarily weak and numb, with bilateral Babinski signs and sometimes with sphincteric incontinence. Blows to the occiput may cause temporary blindness. The symptoms disappear after a few hours. It seems unlikely that these transient symptoms represent a direct localized concussive effect, caused either by indentation of the skull or by impact of these parts of the brain against the inner table of the skull. A concussion of the cervical portion of the spinal cord is another suggested but improbable mechanism of transient paraplegia. The blindness and paraplegia are usually followed by a throbbing vascular type of headache. Transient migrainous visual phenomena, aphasia, or hemiparesis, followed by a headache, are observed sometimes in athletes who participate in competitive contact sports. Probably all of these phenomena are due to an attack of migraine or migraine equivalent induced by a blow to the head. This can be perplexing for a few hours, especially if it is the first such attack of migraine in a child. Another clinical possibility, particularly in acute quadriplegic cases, is cartilagenous embolism of the cervical cord (page 1321).

Delayed Hemiplegia In our experience, most examples of these disorders have occurred in male adolescents or young adults who, some hours after a relatively minor athletic or road injury, developed a massive hemiplegia, homonymous hemianopia, or aphasia (with left-sided lesions). Imaging or ultrasound may reveal a *dissection of the internal carotid artery*. The dissection may occur in the intracranial portion of the carotid artery and should be sought by MR angiography or arteriography if the hemiparesis has no other explanation. In other instances, particularly after a blow to the neck, a mural thrombus forms in the carotid, which, in turn, may shed an embolus to the anterior or middle cerebral artery. In yet other instances, the hemiplegia has no explanation other than the blow to the head.

Other causes of delayed hemiplegia are a late evolving epidural or subdural hematoma and, in more severe injuries, an intracerebral hemorrhage (occasionally from a pre-existent arteriovenous malformation). Most of these are associated with a diminution in the level of consciousness.

Fat Embolism With fractures of large bones, there may be, after 24 to 72 h, an acute onset of pulmonary symptoms (dyspnea and hyperpnea) followed by coma with or without focal signs; this sequence is due to systemic fat embolism, first of the lungs and then of the brain. In some cases the onset of pulmonary symptoms is associated with a petechial rash over the thorax, and one in three cases is said to show fat globules in the urine. Respiratory distress is the most important and often the only feature of the fat embolism syndrome, evident in the chest film as fluffy infiltrates in both lungs. In the brain, the fat emboli cause widespread petechial hemorrhages, involving both white and gray matter and a few larger infarcts. Most cases of fat embolism recover spontaneously in 3 or 4 days, although a mortality

rate of up to 10 percent is quoted, usually related to the underlying injuries.

Patients Who Have Been Comatose from the Time of Head Injury

Here the central problem, so ably set forth by [Symonds](#), is the relationship between concussion and contusion. Since consciousness is abolished at the moment of injury, one can hardly doubt the existence of concussion in such cases; but when hours and days pass without consciousness being regained, the second half of the usual definition of concussion—namely, that the paralysis of cerebral function be transitory—is not satisfied. Careful pathologic examination of such cases usually discloses evidence of increased intracranial pressure and of cerebral contusions, lacerations, subarachnoid hemorrhage, zones of infarction, and scattered intracerebral hemorrhages—both at the point of injury (coup) and on the opposite side (contrecoup), in the corpus callosum, and between these points, along the *line of force* of the injury. In some patients, the diffuse axonal type of injury is the most prominent abnormality; in others, there are separate but strategically placed ischemic and hemorrhagic lesions in the upper midbrain and lower thalamic region, as already mentioned. The tissue around the contusions is swollen, and in postmortem preparations the white matter in these regions appears pale in myelin stains. Varying amounts of blood in the subdural space are usually present. A major shift of the thalamus and midbrain is frequently present, the latter with compression of the opposite cerebral peduncle against the free margin of the tentorium as well as secondary midbrain hemorrhages and zones of necrosis; in some cases, there is frank transtentorial herniation.

It should be kept in mind that severe head injury is associated with an immediate arrest of respiration and sometimes with bradyarrhythmia and cardiac arrest. The effects on the brain of these systemic changes may in themselves be sufficiently profound to cause coma. Also, head injury often complicates alcohol and drug ingestion, so that the possibility of a toxic or metabolic encephalopathy as the cause (or a contributing cause) of stupor must always be considered.

Within this category of severe head injury and protracted coma, three clinical subgroups can be recognized: one in which cerebral and other bodily injuries are incompatible with survival; *a second* in which improvement sets in within a few days or a week or two, followed by variable degrees of recovery but leaving the patient with residual neurologic signs; and *a third* and relatively small group in which the patients remain permanently comatose, stuporous, or profoundly reduced in their cerebral capacities. Of course there are many degrees of injury that fall between these three arbitrary subgroups. In all of these patients, following the initial period of stabilization, the matters of interest are the clinical and radiologic assessment, with the purpose of uncovering a surgically remediable lesion—namely a subdural or epidural hematoma—or a treatable intraparenchymal hematoma. In most cases, the discovery of such a mass lesion mandates surgical removal. But unless it is the only lesion, the procedure often proves to be insufficient and coma is likely to persist because of the associated cerebral damage. The recognition and management of these hematomas are described further on in this section.

The *first subgroup* comprises patients who are so severely injured that their lives are obviously endangered. When first seen, such a patient may be in shock (possibly from rupture of a visceral organ or injury of the cervical cord), with hypotension, hypothermia, fast, thready pulse, and pale, moist skin. If this state persists along with deep coma, widely dilated fixed pupils, absent eye movements and corneal and pharyngeal reflexes, flaccid limbs, stertorous and irregular respirations or respiratory failure, death usually follows in a short time. Once respiration ceases and the EEG becomes isoelectric, the clinical state corresponds to brain death, as described on page 371. However, the diagnosis of brain death should not be made immediately after injury, in order to allow time to exclude the effects of anoxia, drug or alcohol intoxication, and hypotension. In some of these patients, the blood pressure and respirations stabilize, and the degree of cerebral injury can then be evaluated over a period of hours by observing the depth of coma and the temperature, pulse, and blood pressure. Deep coma with subnormal temperature and rising pulse rate are grave prognostic signs, as are a rapidly rising temperature and pulse rate with rapid, irregular respirations. In some fatal cases, the temperature continues to rise until the end, when there is circulatory collapse.

Small linear or rounded hemorrhages are seen in a nonenhanced CT scan. These hemorrhages are evidently consequent upon rotational forces acting on the upper brainstem and corpus callosum ([Fig. 35-6](#)).

Figure 35-6 CT scan from a patient with diffuse axonal injury. There are multiple small hemorrhagic areas (one of which is circled) in the cerebral white matter and corpus callosum.

In this category of severe cerebral injury, where the patients survive for only a few hours or days, postmortem examination commonly discloses cerebral contusion and focal hemorrhage, necrosis of tissue, and brain swelling. In the Traumatic Coma Data Bank, which included 1030 gravely injured patients with Glasgow Coma Scale scores of 8 or less, 21 percent had subdural hematomas, 11 percent had intracerebral clots, and 5 percent had epidural hematomas. Notable, however, is the fact that half the patients had no mass lesions on the CT scan. On the basis of CT criteria, these patients were thought to have diffuse axonal injury, although it coexisted with mass lesions in many cases. In 50 consecutive autopsies of such severely injured patients, summarized in an earlier era by [Rowbotham](#), all but two showed macroscopic changes. The lesions in these cases consisted of surface contusions (48 percent), lacerations of the cerebral cortex (28 percent), subarachnoid hemorrhage (72 percent), subdural hematoma (15 percent), extradural hemorrhage (20 percent), and skull fractures (72 percent). As these figures indicate, several of these changes were found in the same patient. Moreover, trauma of extracranial organs and tissues is frequent and obviously contributes to the fatal outcome.

In respect to *the second subgroup*, i.e., the relatively less severe and seldom fatal head injuries, all gradations in tempo and degree of recovery can be observed. In the least severely injured of this group, recovery of consciousness begins in a few hours, although there may be a relapse within the first day or two as a result of swelling of the contused brain tissue, enlargement of a subdural hematoma, brain hemorrhage, or infarction, the last provoked by arterial spasm in relation to subarachnoid hemorrhage. The CSF is usually bloody. Eventually, recovery may be nearly complete, but the period of traumatic amnesia covers a span of several days or even weeks. It should be repeated that occasionally penetrating types of injuries and depressed fractures may seriously damage the brain without causing concussion at all, but here we are considering only the blunt, nonpenetrating head injuries.

In this second subgroup, the sequence of clinical events is the same as that described in relation to concussion except that their duration is more protracted. Stupor gives way to a confusional state that may last for weeks, and it may for a variable period be associated with aggressive behavior and uncooperativeness (traumatic delirium). The period of traumatic amnesia is proportionately longer than in the less severely injured. It is during the period of recovery of consciousness that focal neurologic signs (hemiparesis, aphasia, abulia, etc.) become more obvious, though some unilateral signs may have been discerned during the comatose period. Once the patient improves to the point of being able to converse, he is demonstrably slow in thinking, with few mental associations; unstable in emotional reactions; and faulty in judgment—a state sometimes referred to as “traumatic dementia.”

Finally there is that relatively small, distressing group of *severely brain-injured patients in whom the vital signs become normal but who never regain full consciousness*. As the weeks pass, the prospects become more bleak. Such a patient, especially if young, may still emerge from coma after 6 to 12 weeks and make a surprisingly good though usually an incomplete recovery, but such instances are decidedly rare. Some of those who survive for long periods open their eyes and move their heads and eyes from side to side but betray no evidence of seeing or recognizing even the closest members of their families. They do not speak and are capable of only primitive postural or reflex withdrawal movements. Jennett and Plum referred to this as the “persistent vegetative state” (see page 369). Fourteen percent of the patients in the Traumatic Coma Data Bank were left in this state. Hemiplegia or quadriplegia with varying degrees of decerebrate or decorticate posturing is usually demonstrable. Life is mercifully terminated after several months or years by some medical complication. Our colleague, R. D. Adams, has examined the brains of 14 patients who remained in coma and in vegetative states from one to 14 years. All showed extensive zones of necrosis and hemorrhage in

the upper brainstem.

In generalizing about this category of head injury, i.e., patients who are and have been comatose from the time of injury, the effects of contusion, hemorrhage, and brain swelling often become evident within 18 to 36 h after the injury and then may progress for several days. If the patients survive this period, their chances of dying from complications of these effects—such as increased intracranial pressure, herniations of the temporal lobe, subdural hemorrhage, hypoxia, and pneumonia—are greatly reduced. The mortality rate of those who reach the hospital in coma is about 20 percent, and most of the deaths occur in the first 12 to 24 h as a result of direct injury to the brain in combination with other nonneurologic injuries. Of those alive at 24 h, the overall mortality falls to 7 to 8 percent; after 48 h, only 1 to 2 percent succumb. There is some evidence that transfer of such patients to an intensive care unit, where they can be monitored by personnel experienced in the handling of head injury, improves the chances for survival (see further on).

Concussion Followed by a Lucid Interval and Serious Cerebral Damage

This group is smaller than the other two but is of great importance because it includes a disproportionate number of patients who are in urgent need of surgical treatment. The initial coma may have lasted only a few minutes or, exceptionally, there may have been none at all—in which instance one might wrongly conclude that since there was no concussion, there is no possibility of traumatic hemorrhage or other type of brain injury. Patients who display this serious sequence of events, referred to as “talk and die” by [Marshall](#) and associates, deteriorate because of the delayed expansion of a small subdural hematoma, a worsening brain edema, or occasionally the late appearance of an epidural clot. Among 34 such patients in the Traumatic Coma Data Bank ([Marshall et al](#)), the majority showed substantial degrees of midline shift on the initial CT scan, reflecting the presence of brain edema and contusion. A similar condition of delayed intracerebral hematoma discussed further on (*Spätaepoplexie*) is a feature of a severe initial head injury that engenders coma from the onset and places the patient at great risk. The following conditions must be considered in all cases of these delayed types.

Acute Epidural Hemorrhage As a rule, this condition is due to a temporal or parietal fracture with laceration of the middle meningeal artery or vein. Less often, there is a tear in a dural venous sinus. The injury, even when it fractures the skull, may not have produced coma initially, or it may be part of a devastating craniocerebral injury. A far more typical example is that of a child who has fallen from a bicycle or swing or has suffered some other hard blow to the head and was unconscious only momentarily. A few hours or a day later (exceptionally, with venous bleeding, the interval may be several days or a week), headache of increasing severity develops, with vomiting, drowsiness, confusion, aphasia, seizures (which may be one-sided), hemiparesis with slightly increased tendon reflexes, and a Babinski sign. As coma develops, the hemiparesis may give way to bilateral spasticity of the limbs and Babinski signs. When the patient remains untreated, the respirations become deeper and stertorous, then shallow and irregular; finally, they cease. The pulse is often slow (below 60 beats per minute) and bounding, with a concomitant rise in systolic blood pressure (Cushing effect). The pupil may dilate on the side of the hematoma. Physicians need not be reminded that lumbar puncture is contraindicated in this setting, now that CT and MRI are available. Death, which is almost invariable if the clot is not removed surgically, comes at the end of a comatose period and is due to respiratory arrest. The visualization of a fracture line across the groove of the middle meningeal artery and knowledge of which side of the head was struck (the clot is usually on that side) are of aid in diagnosis and lateralization of the lesion. However, meningeal vessels may be torn without fracture. The CT scan reveals a lens-shaped clot with a smooth inner margin ([Fig. 35-7](#)). The surgical procedure consists of placement of burr holes or, preferably, a craniotomy, drainage of the hematoma, and identification and ligation of the bleeding vessel. The operative results are excellent except in the cases with extended fractures and laceration of the dural venous sinuses, in which the epidural hematoma may be bilateral rather than unilateral, as it ordinarily is. If coma, bilateral Babinski signs, spasticity, or decerebrate rigidity supervene before operation, it usually means that displacement of central structures and crushing of the midbrain have already occurred; prognosis for life is then poor. Small epidural hemorrhages, followed by serial CT scanning, will be seen to enlarge gradually for a week or two and then be absorbed.

Figure 35-7 Acute epidural hematoma; unenhanced CT scan showing a typical lenticular-shaped frontal epidural clot.

Acute and Chronic Subdural Hematomas The problems created by acute and chronic subdural hematomas are so different that they must be discussed separately. In *acute subdural hematoma*, which may be unilateral or bilateral, there may be a brief lucid interval between the blow to the head and the advent of coma. Or, more often, the patient is comatose from the time of the injury and the coma deepens progressively. Frequently the acute subdural hematoma is combined with epidural hemorrhage, cerebral contusion, or laceration. The clinical effects of these several lesions are difficult to distinguish; there are some patients in whom it is impossible to state before operation whether the clot is epidural or subdural in location. Subdural clots more than 5 mm thick can be accurately visualized by the CT scan in more than 90 percent of cases ([Fig. 35-8](#)). A large acute clot causes a pineal shift as well as marked compression of one lateral ventricle; but if the lesion is bilateral, there may be no shift and the ventricles appear symmetrical.

Figure 35-8 Acute subdural hematoma over the right convexity, with substantial mass effect (displacement) of brain tissue, but little edema.

Acute, rapidly evolving subdural hematomas are due to tearing of bridging veins, and symptoms are caused by compression of the brain by an expanding clot of fresh blood. Unlike epidural arterial hemorrhage, which is steadily progressive, venous bleeding is usually arrested by the rising intracranial pressure.

Exceptionally, *the subdural hematoma forms in the posterior fossa* and gives rise to headache, vomiting, pupillary inequality, dysphagia, cranial nerve palsies, and, rarely, stiff neck and ataxia of the trunk and gait if the patient is well enough to be tested for these functions. Because of their apposition to bone or their axial orientation along the tentorial dura, posterior fossa clots are more likely to be missed in CT scans than clots over the cerebral convexities.

In *chronic subdural hematoma*, the traumatic etiology is often less clear. The head injury, especially in elderly persons and in those taking anticoagulant drugs, may have been trivial and may even have been forgotten. A period of weeks then follows when headaches (not invariable), light-headedness, slowness in thinking, apathy and drowsiness, and occasionally a seizure or two are the main symptoms. The initial impression may be that the patient has a vascular lesion or brain tumor or is suffering from drug intoxication, a depressive illness, or Alzheimer disease. As with acute subdural hematoma, the disturbances of mentation and consciousness

(drowsiness, inattentiveness, incoherence of thinking, and confusion) are more prominent than focal or lateralizing signs, and they may fluctuate. The focal signs usually consist of hemiparesis and rarely of an aphasic disturbance. Homonymous hemianopia is seldom observed, probably because the geniculocalcarine pathway is deep and not easily compressed; similarly, hemiplegia, i.e., complete paralysis of one arm and leg, is usually indicative of a lesion within the cerebral hemisphere rather than a compressive lesion on its surface. An important feature of the hemiparesis is that it may sometimes be ipsilateral, depending on whether the contralateral cerebral peduncle has been compressed against the free edge of the tentorium by horizontal displacement (Kernohan-Woltman false localizing sign; see page 367). If the condition progresses, the patient becomes stuporous or comatose but often with striking fluctuations of awareness.

Dilatation of the ipsilateral pupil is a more reliable indicator of the side of the hematoma than the hemiparesis, though the side of pupillary abnormality may also be misleading (occurring on the opposite side in 10 percent of cases, according to Pevehouse and coworkers). Convulsions are seen occasionally, most often in alcoholics or in patients with cerebral contusions, but they cannot be regarded as a cardinal sign of subdural hematoma. Rare cases of internuclear ophthalmoplegia and of chorea have been reported but have not occurred in our material. Presumably they are a result of distortion of deep structures. Also, transient disturbances of neurologic function simulating transient ischemic attacks (TIAs) may occur. In infants and children, enlargement of the head, vomiting, and convulsions are prominent manifestations of subdural hematoma (see page 1053).

CT scanning with contrast infusion and MRI are the most reliable diagnostic procedures. On CT scans, the clot is initially hyperdense but becomes isodense after a period of time ([Fig. 35-9](#)), during which it may be difficult to detect except by the tissue shifts it causes; It then becomes progressively hypodense (with respect to the cortex) over the first 2 to 6 weeks. The evolution of signal changes in the MRI are similar to the sequential changes of parenchymal hematomas. The acute clot is hypointense on T2-weighted images, reflecting the presence of deoxyhemoglobin. Over the subsequent weeks, all image sequences show it as hyperintense as a result of methemoglobin formation. Eventually the chronic clot again becomes hypointense on the T1-weighted images. With contrast infusion, both imaging procedures usually reveal the vascular and reactive border surrounding the clot. Usually, by the fourth week, sometimes later, the hematoma becomes hypodense, typical of a chronic subdural hygroma.

Figure 35-9 Subacute subdural hematoma. CT scans after administration of intravenous contrast material. The lesion is isodense, but its margin can be appreciated with contrast enhancement. Note displacement of cerebral structures.

Other formerly used investigative measures are seldom necessary but are mentioned here for completeness and in the event that the diagnosis is made in the course of evaluating some other neurologic problem. Skull films are helpful when there is calcification surrounding a chronic hematoma, a calcified pineal that is shifted to one side, or an unexpected fracture line is found. The EEG is usually abnormal bilaterally, sometimes with reduced voltage or electrical silence over the hematoma and high-voltage slow waves over the opposite side, because of the damping effects of the clot and displacement of the brain, respectively. In an arteriogram, the cortical branches of the middle cerebral artery are separated from the inner surface of the skull, and the anterior cerebral artery may be displaced contralaterally. The CSF may be clear and acellular, but more often is bloody or xanthochromic, depending on the presence or absence of recent or old contusions and subarachnoid hemorrhage; the pressure may be elevated or normal. A xanthochromic fluid with relatively low protein content should always raise the suspicion of chronic subdural hematoma.

The chronic subdural hematoma becomes encysted by fibrous membranes (pseudomembranes) that grow from the dura. Some hematomas—probably the ones in which the initial bleeding was slight (see below)—resorb spontaneously. Others expand slowly and act as space-occupying masses ([Fig. 35-10](#)). Gardner, in 1932, first postulated that the gradual enlargement of the hematoma was due to the accession of fluid, particularly CSF—which was drawn into the hemorrhagic cyst by its increasing osmotic tension—as red blood cells hemolyzed and protein was liberated. This hypothesis, which came to be widely accepted, is not supported by the available data. Rabe and colleagues demonstrated that the breakdown of red cells contributes little if at all to the accumulation of fluid in the subdural space. According to the latter authors, the most important factor in the accumulation of subdural fluid is a pathologic permeability of the developing capillaries in the outer pseudomembrane. The CSF plays no discernible role in this process, contrary to the original view of Munro and Merritt. In any event, as the hematoma enlarges, the compressive effects increase. Severe cerebral compression and displacement with temporal lobe–tentorial herniation are the usual causes of death.

Figure 35-10 Chronic subdural hematomas over both cerebral hemispheres, without shift of the ventricular system. Chronicity results in hypodense appearance of the clots. Some old blood can still be seen on the right side. The bilaterally balanced masses result in an absence of horizontal displacement, but they may compress the upper brainstem.

Why somewhat less than one-half of all subdural hematomas remain solid and nonenlarging and the remainder liquefy and then enlarge is not known. The experimental observations of Labadie and Glover suggest that the volume of the original clot is a critical factor: the larger its initial size, the more likely that it will enlarge. An inflammatory reaction, triggered by the breakdown products of blood elements in the clot, appears to be an additional stimulus for growth as well as for neomembrane formation and its vascularization.

Subdural hygroma (an encapsulated collection of xanthochromic fluid in the subdural space) may form after an injury as well as after meningitis (in an infant or young child). More often subdural hygromas appear without infection, presumably due to a ball-valve effect of an arachnoidal tear that allows fluid to collect in the space between the arachnoid and the dura; brain atrophy is conducive to this process. Occasionally a hygroma originates from a tear in an arachnoidal cyst. It may be difficult to differentiate a long-standing subdural hematoma from hygroma, and some chronic subdural hematomas are probably the result of repeated small hemorrhages that arise from the membranes of hygromas. In the past, subdural hygroma also occurred as a complication of pneumoencephalography. Shrinkage of the hydrocephalic brain after ventriculoperitoneal shunting is also conducive to the formation of a subdural hematoma or hygroma, in which case drowsiness, confusion, irritability, and low-grade fever are relieved when the subdural fluid is aspirated or drained. In adults, hygromas are usually asymptomatic and do not require treatment.

Treatment of Subdural Hematoma In most cases of acute hematoma, it is sufficient to place burr holes and evacuate the clot before deep coma has developed. Treatment of larger hematomas consists of wide craniotomy to permit control of the bleeding and removal of the clot. As one would expect, the interval between loss of consciousness and the surgical drainage of the clot is perhaps the most important determinant of outcome in serious cases. Thin, crescentic clots can be observed over several weeks and surgery undertaken only if focal signs develop or indications of increasing intracranial pressure arise (headache, vomiting, and bradycardia). Small subdural hematomas causing no symptoms and followed by CT scans will self-absorb, leaving only a deep yellow, sometimes calcified membrane attached to the inner dural surface.

The surgical results are less certain than in chronic subdural hematoma. If the clot is too small to explain the coma or other symptoms, there is probably extensive contusion and laceration of the cerebrum. In other, more chronic hematomas, a craniotomy must be performed and an attempt made to strip the membranes that surround the clot. This diminishes the likelihood of reaccumulation of fluid but is not always successful. Other causes of operative failure are swelling of the compressed hemisphere or failure of the hemisphere to expand after removal of a large clot. Elderly patients may be slow to recover after removal of the hematoma or may have a prolonged period of confusion. Postoperative expansion of the brain can be followed by serial CT scans.

Although no longer a common practice, the administration of corticosteroids is an alternative to surgical removal of subacute and chronic subdural hematomas in patients with minor symptoms or with some contraindication to surgery. Headache and other symptoms such as gait difficulty or limb clumsiness may resolve satisfactorily after several weeks of medication and may remain abated when the steroids are slowly reduced.

Cerebral Contusion Severe closed head injury is almost universally accompanied by cortical contusions and surrounding edema. The mass effect of contusional swelling, if sufficiently large, is a major factor in the genesis of tissue shifts and raised intracranial pressure. The CT appearance of contusion has already been described (page 931; see also [Fig. 35-4](#) and [Fig. 35-5](#)). In the first few hours after injury, the bleeding points in the contused area may appear small and innocuous. The main concern, however, is the tendency for a contused area to swell or to develop a hematoma. This may give rise to clinical deterioration hours to days after the injury, sometimes abrupt in onset and concurrent with the appearance of swelling of the damaged region on the CT scan. It has been claimed, on uncertain grounds, that the swelling in the region of an acute contusion is precipitated by excessive administration of intravenous fluids (fluid management is considered further on in this chapter).

Traumatic Intracerebral Hemorrhage One or several intracerebral hemorrhages may be apparent immediately after head injury or hemorrhage may be delayed in its development by several days (*Spätaoplexie*). It may occur in the subcortical white matter of one lobe of the brain or in deeper structures, such as the basal ganglia or thalamus. The injury is nearly always severe; blood vessels as well as cortical tissue are torn.

The clinical picture is similar to that of hypertensive brain hemorrhage (deepening coma with hemiplegia, a dilating pupil, bilateral Babinski signs, stertorous and irregular respirations). It may be manifest by an abrupt rise in intracranial pressure. In elderly patients, it is sometimes difficult to determine whether a fall was the cause or the result of an intracerebral hemorrhage. Craniotomy with evacuation of the clot has given a successful result in a few cases, but the advisability of surgery is governed by several factors, including the level of consciousness, the time from the initial injury, and the associated damage that is shown by imaging studies. The wider application of intracranial pressure monitoring and of CT scans at intervals after the injury should facilitate diagnosis and perhaps help to elucidate the pathogenesis of the delayed hemorrhage(s).

Acute Brain Swelling in Children This condition is seen in the first hours after injury and may prove rapidly fatal. The CT scan shows enlargement of both hemispheres and compression of the basal cisterns. There is usually no papilledema in the early stages, during which the child hyperventilates, vomits, and shows extensor posturing. The presumption has been that this represents a loss of regulation of cerebral blood flow and a massive increase in the blood volume of the brain. The administration of excessive water in intravenous fluids may contribute to the problem and should be avoided. We have not observed this complication in head-injured adults.

Penetrating Wounds of the Head

Missiles and Fragments All the descriptions in the preceding pages apply to blunt, nonpenetrating injuries of the skull and their effects on the brain. The disorders included in this section are more the concern of the neurosurgeon than the neurologist. In the past, the care of penetrating craniocerebral injuries was mainly the preoccupation of the military surgeon, but—with the increasing amount of violent crime in western society—such cases have become commonplace on the emergency wards of general hospitals.

In civilian life, *missile injuries* are essentially caused by bullets fired from rifles or handguns at high velocities. Air is compressed in front of the bullet so that it has an explosive effect upon entering tissue and causes damage for a considerable distance around the missile track. *Missile fragments*, or *shrapnel*, are pieces of exploding shells, grenades, or bombs and are the usual causes of penetrating cranial injuries in wartime. The cranial wounds that result from missiles and shrapnel have been classified by [Purvis](#) as (1) tangential injuries, with scalp lacerations, depressed skull fractures, and meningeal and cerebral lacerations; (2) penetrating injuries with in-driven metal particles, hair, skin, and bone fragments; and (3) through-and-through wounds.

If the brain is penetrated at the lower levels of the brainstem, death is instantaneous because of respiratory and cardiac arrest. Even through-and-through wounds at higher levels, as a result of energy dissipated in the brain tissue, damage vital centers sufficiently to cause death immediately or within a few minutes in 80 percent of cases. If vital centers are untouched, the immediate problem is intracranial bleeding and rising intracranial pressure from swelling of the traumatized brain tissue.

Once the initial complications are dealt with, the surgical problems, as outlined by [Meirowsky](#), are reduced to three: (1) prevention of infection by rapid and radical (definitive) debridement, accompanied by the administration of broad-spectrum antibiotics; (2) control of increased intracranial pressure and shift of midline structures by removal of clots of blood and the vigorous administration of mannitol or other dehydrating agents as well as dexamethasone; and (3) the prevention of life-threatening systemic complications.

When first seen, the majority of patients with penetrating cerebral lesions are comatose. A small metal fragment may penetrate the skull without causing concussion, but this is not true of high-velocity missiles. In a series of 132 cases of the latter type analyzed by [Frazier and Ingham](#), consciousness was lost in 120. The depth and duration of coma seemed to depend upon the degree of cerebral necrosis, edema, and hemorrhage. In the Traumatic Coma Data Bank Series, the mortality rate in 163 patients who were initially comatose from a cranial gunshot wound was 88 percent—more than twice the mortality that results from severe blunt head injury. Upon emerging from coma, the patient passes through states of stupor, confusion, and amnesia, not unlike those of severe closed head injuries. Headache, vomiting, vertigo, pallor, sweating, slowness of pulse, and elevation of blood pressure are other common findings. Focal or focal and generalized seizures occur in the early phase of the injury in some 15 to 20 percent of cases.

Recovery may take many months. Frazier and Ingham comment on the “loss of memory, slow cerebration, indifference, mild depression, inability to concentrate, sense of fatigue, irritability, vasomotor and cardiac instability, frequent seizures, headaches and giddiness, all reminiscent of the residual symptoms from severe closed head injury with contusions.” Every possible combination of focal cerebral symptoms may be caused by such lesions. The classic articles by [Feiring and Davidoff](#) and also by [Russell](#) and by [Teuber](#), listed at the end of this chapter, are still very useful references on this subject.

Epilepsy is the most troublesome sequela and is described below. Ascroft and also Caviness, in reviewing World War II cases, found that approximately half of all patients with wounds that had penetrated the dura eventually developed epilepsy, most often focal in nature; the figures reported by [Caviness](#) for Korean War veterans are about the same (see discussion below).

CSF rhinorrhea, discussed earlier and in [Chap. 30](#), may occur as an acute manifestation of a penetrating injury that produces a fracture through the frontal, ethmoid, or sphenoid bones. Cairns listed these acute cases as a separate group in his classification of CSF rhinorrheas, the others being (1) a delayed form after craniocerebral injury, (2) a form that follows sinus and cranial surgery, and (3) a spontaneous variety. *Pneumoencephalocele (aerocele)*—i.e., air entering the cerebral subarachnoid space or ventricles spontaneously or as a result of sneezing or blowing the nose—is evidence of an opening from the paranasal sinus through the dura.

Crushing Injuries of the Skull Aside from the absence of concussion, these relatively rare cerebral lesions present no special clinical features or neurologic problems not already discussed.

Birth Injuries These involve a unique combination of physical forces and circulatory-oxygenation factors and are discussed separately in [Chap. 38](#).

SEQUELAE OF HEAD INJURY

Posttraumatic Epilepsy Epilepsy is the most common delayed sequela of craniocerebral trauma, with an overall incidence of about 5 percent in patients with closed head injuries and 50 percent in those who had sustained a compound skull fracture and wound of the brain. The basis is nearly always a contusion or laceration of the cortex. As one might expect, the risk of developing posttraumatic epilepsy is related to the severity of the head injury. In a civilian cohort of 2747 head-injured patients described by [Annegers and colleagues](#), the risk of seizures after severe head injury (loss of consciousness or amnesia for more than 24 h, including subdural hematoma and brain contusion) was 7 percent within 1 year and 11.5 percent in 5 years. If the injury was only moderate (unconsciousness or amnesia for 30 min to 24 h or causing only a skull fracture), the risk fell to 0.7 and 1.6 percent, respectively. After mild injury (loss of consciousness or amnesia of less than 30 min) the incidence of seizures was not significantly greater than in the general population. In a subsequent study (1998), Annegers et al expanded the original cohort to include 4541 children and adults with cerebral trauma. The results were much the same as those of the first study except that in patients with mild closed head injuries, there was only a slight excess risk of developing seizures—a risk that remained elevated only until the fifth year after injury. The likelihood of epilepsy is said to be greater in parietal and posterior frontal lesions, but it may arise from lesions in any area of the cerebral cortex. Also, the frequency of seizures is considerably higher after penetrating cranial injury, as cited above.

The interval between the head injury and the first seizure varies greatly. A small number of patients have a generalized seizure within moments of the injury (*immediate epilepsy*). Usually this amounts to a brief tonic extension of the limbs, with slight shaking movements immediately after concussion, followed by awakening in a mild confusional state. Whether this represents a true epileptic phenomenon or, as appears more likely, is the result of arrest of cerebral blood flow is unclear. Some 4 to 5 percent of hospitalized head-injured individuals are said to have one or more seizures within the first week of their injury (*early epilepsy*). Immediate seizures have a good prognosis; on the other hand, late epilepsy is significantly more frequent in patients who had experienced early epilepsy ([Jennett](#)). In medical writings, the term *posttraumatic epilepsy* usually refers to late epilepsy, i.e., to seizures that develop several weeks or months after the head injury (1 to 3 months in most cases). Approximately 6 months after injury, half the patients who will develop epilepsy have had their first attack, and by the end of 2 years the figure rises to 80 percent ([Walker](#)). The interval between head injury and development of seizures is said to be longer in children. The longer the interval, the less certain one is of its relation to the traumatic incident. Data derived from a 15-year study of military personnel with severe (penetrating) brain wounds indicate that patients who escape seizures for 1 year after injury can be 75 percent certain of remaining seizure-free; patients without seizures for 2 years can be 90 percent certain; and for 3 years, 95 percent certain. For the less severely injured (mainly closed head injuries), the corresponding times are 2 to 6 months, 12 to 17 months, and 21 to 25 months ([Weiss et al](#)).

Posttraumatic seizures (both focal and generalized) tend to decrease in frequency as the years pass, and a significant number of patients (10 to 30 percent, according to Caveness) eventually stop having them. Individuals who have early attacks (within a week of injury) are more likely to have a complete remission of their seizures than those whose attacks begin a year or so after injury. A low frequency of attacks is another favorable prognostic sign. Alcoholism has an adverse effect on this seizure state. We have observed some 25 patients with posttraumatic epilepsy in whom seizures had ceased altogether for several years, only to recur in relation to drinking. In these patients the seizures were precipitated by a weekend or even one evening of heavy drinking and occurred, as a rule, not when the patient was intoxicated but in the “sobering-up” period.

The Nature of the Epileptogenic Lesion This has been elusive. From the examination of old cortical contusions (*plaques jaunes*), one cannot, on morphologic grounds, determine whether the lesion had been epileptogenic. Electrocorticograms of the brain in regions adjacent to old traumatic foci reveal a number of electrically active zones adjacent to the scars. Microscopically these foci show neuronal loss and an increase of astrocytes. It is postulated that abnormalities of dendritic branching provide the groundwork for the excitatory focus. Other investigators favor deafferentation of residual cortical neurons as the cause of their increased irritability.

Treatment and Prophylaxis Usually the seizures can be controlled by a single anticonvulsant medication, and relatively few are recalcitrant to the point of requiring excision of the epileptic focus. The surgical results vary according to the methods of selection and techniques of operation. Under the best of neurosurgical conditions three decades ago, with careful selection of cases, Rasmussen (also Penfield and Jasper) was able to eradicate seizures in 50 to 75 percent of cases by excision of the focus, and the results currently are even better.

The use of anticonvulsant drugs to prevent the first seizure and subsequent epilepsy has its proponents and opponents. In one study, patients taking phenytoin developed fewer seizures at the end of the first year than a placebo group, but a year after medication was discontinued, the incidence was the same in the two groups. In another prospective double-blind study, one group of patients was given 60 mg phenobarbital and 200 mg phenytoin daily for 18 months and another group was untreated; at the end of 3- and 6-year periods, there was no significant difference in the occurrence of seizures between treated and untreated groups ([Penry et al](#)). Also, in a study of a large number of patients with penetrating head injuries, the prophylactic use of anticonvulsants was ineffective in preventing early seizures ([Rish and Caveness](#)).

Autonomic Dysfunction Syndrome in Traumatic Coma A troublesome consequence of severe head injury, observed most often in comatose patients and in those with the persistent vegetative state, is the occurrence of episodic violent extensor posturing, profuse diaphoresis, hypertension, and tachycardia lasting minutes to an hour. A slight fever may accompany the spells. Families and staff are greatly disturbed by the display, particularly when accompanying grimacing suggests suffering. These spells of hypersympathetic activity and posturing may be precipitated by painful stimuli or distension of a viscus, but often they arise spontaneously. The syndrome is often identified as a seizure and in many texts is still incorrectly referred to as “diencephalic epilepsy,” but it is more likely the result of decortication, allowing the hypothalamus to function independently of normal inhibitory mechanisms. A survey of 35 such patients by [Baugley and colleagues](#) identified diffuse axonal injury and a period of hypoxia as being the main associated forms of injury, and this has been our experience as well. Narcotics and diazepam have a slight beneficial effect, but bromocriptine, which may be used in combination with sedatives or with small doses of morphine, has been most effective ([Rossitch and Bullard](#)).

Extrapyramidal and Cerebellar Disorders Following Trauma The question of a causative relationship between cerebral trauma and the development of Parkinson disease has been a controversial issue for many years—usually with the conclusion that it does not exist and that any apparent relationship is superficial and coincidental. Most such patients probably had early symptoms of Parkinson disease, brought to light by the head injury. There are, however, rare cases, such as the one reported by [Doder and colleagues](#), in which traumatic necrosis of the lenticular and caudate nuclei was followed, after a period of 6 weeks, by the onset of predominantly contralateral parkinsonian signs, including tremor, which progressed slowly and were unresponsive to L-dopa. An exception to these statements may be a parkinsonian syndrome in ex-boxers, as a manifestation of the “punch-drunk” syndrome (see below). Cerebellar ataxia is a rare consequence of cranial trauma unless the latter was complicated by cerebral anoxia or a hemorrhage strategically placed in the deep midbrain or cerebellum. When cerebellar ataxia is due to the trauma itself, it is frequently unilateral and the result of injury to the superior cerebellar peduncle. An ataxia of gait may also reflect the presence of a communicating hydrocephalus.

“Punch-Drunk Encephalopathy” (Dementia Pugilistica) The cumulative effects of repeated cerebral injuries, observed in boxers who had engaged in many bouts over a long period of time, constitute a type of head injury that is difficult to classify. What is referred to is the development, after many years in the ring (sometimes toward the end of the boxer's career, more often within a few years of retirement), of dysarthric speech and a state of forgetfulness, slowness in thinking, and other signs of dementia. Movements are slow, stiff, and uncertain, especially those involving the legs, and there is a shuffling, wide-based gait. Often a parkinsonian syndrome emerges (found in 20 of the 52 cases that Roberts and coworkers abstracted from the literature up to 1969) and sometimes a moderately disabling ataxia. The plantar reflexes may be extensor on one or both sides. The EEG contains slow waves of theta and sometimes of delta type. The clinical syndrome was reanalyzed by [Roberts and colleagues](#), who found it present to some degree in 37 of the 224 professional boxers they examined. More recent studies have shown that in about one-half of all professional boxers, both active and retired, the CT scan discloses ventricular dilatation and/or sulcal widening and a cavum septi pellucidi (why the latter, which is a developmental anomaly, would be overrepresented in boxers is unclear). These abnormalities had been demonstrated many years before, by pneumoencephalography, and were found to be related to the number of bouts ([Ross et al](#); [Casson et al](#)).

A thorough pathologic study of this disorder has been made by [Corsellis](#) and associates. They examined the brains of 15 retired boxers who had shown the punch-drunk syndrome and identified a group of cerebral changes that appear to explain the clinical findings. Mild to moderate enlargement of the lateral ventricles and thinning of the corpus callosum were present in all cases. Also, practically all of them showed a greatly widened cavum septi pellucidi and fenestration of the septal leaves. Readily identified areas of glial scarring were situated on the inferior surface of the cerebellar cortex. In these areas and well beyond them, Purkinje cells were lost and the granule cell layer was somewhat thinned. Surprisingly, cerebral cortical contusions were found in only a few cases. Notably absent, also, was evidence of previous hemorrhage. Of the 15 cases, 11 showed varying degrees of loss of pigmented cells of the substantia nigra and locus ceruleus, and many of the cells that remained showed the Alzheimer neurofibrillary change; Lewy bodies were not observed, however. The neurofibrillary changes were scattered diffusely

through the cerebral cortex and brainstem but were most prominent in the medial temporal gray matter. Noteworthy was the absence of discrete senile plaques in this material; however, all cases showed extensive immunoreactive deposits of b-amyloid (“diffuse plaques”). In three boxers who developed a parkinsonian syndrome, Davie and colleagues found a reduction of *N*-acetylaspartate in the putamen and pallidum by protein magnetic resonance spectroscopy. This probably reflected a loss of neurons in these regions and differentiated the process from idiopathic Parkinson disease. The pathogenesis of the punch-drunk state remains unclear.

Posttraumatic Hydrocephalus This is an uncommon complication of severe head injury. Intermittent headaches, vomiting, confusion, and drowsiness are the initial manifestations. Later there are mental dullness, apathy, and psychomotor retardation, by which time the CSF pressure may have fallen to a normal level (normal-pressure hydrocephalus). Postmortem examinations have demonstrated an adhesive basilar arachnoiditis. Since a similar syndrome is observed occasionally after the rupture of a saccular aneurysm with subarachnoid hemorrhage, the same mechanisms, i.e., blocking of the aqueduct and fourth ventricle by blood clot and basilar meningeal fibrosis, may also be operative in traumatic hydrocephalus. Response to ventriculoperitoneal shunt may be dramatic. Zander and Foroglou have had extensive experience with this condition and have written informatively about it.

Posttraumatic Nervous Instability (Postconcussion Syndrome) This troublesome and frequent sequela of head injury has been alluded to above as well as in the chapter on headache (page 192). It has also been called the *posttraumatic* or *postconcussion syndrome*, *posttraumatic headache*, *traumatic neurasthenia* ([Symonds](#)), and *traumatic psychasthenia*, among many other names. Headache is the central symptom, either generalized or localized to the part that had been struck. The headache is variously described as aching, throbbing, pounding, stabbing, pressing, or band-like and is remarkable for its variability. The intensification of the headache and other symptoms by mental and physical effort, straining, stooping, and emotional excitement has already been mentioned; rest and quiet tend to relieve it. Such headaches may present a major obstacle to convalescence. Dizziness, another prominent symptom, is usually not a true vertigo but a giddiness or light-headedness. The patient may feel unsteady, dazed, weak, or faint. However, a certain number of patients describe symptoms that are consonant with labyrinthine disorder. They report that objects in the environment move momentarily, and that looking upward or to the side may cause a sense of unbalance; labyrinthine tests may show hyporeactivity; far more often they disclose no abnormalities. McHugh found a high incidence of minor abnormalities by electronystagmography both in concussed patients and in those suffering from whiplash injuries of the neck, but some of the data we find difficult to interpret. Exceptionally, vertigo is accompanied by diminished excitability of both the labyrinth and the cochlea (deafness), and one may assume the existence of direct injury to the eighth nerve or end organ.

The patient with posttraumatic nervous instability is intolerant of noise, emotional excitement, and crowds. Tenseness, restlessness, fragmentation of sleep, inability to concentrate, feelings of nervousness, fatigue, worry, apprehension, and an inability to tolerate the usual amount of alcohol complete the clinical picture. The resemblance of these symptoms to those of anxiety and depression is quite apparent. In contrast to this multiplicity of subjective symptoms, memory and other intellectual functions show little or no impairment, although this has been disputed. Leininger et al, for example, found that most of their 53 patients who suffered minor head injury in traffic accidents performed less well than controls on psychologic tests (category test, auditory verbal learning, copying of complex figures). The fact that those who were merely dazed did as poorly as those who were concussed and that litigation was involved in some cases would lead one to question these results.

The syndrome of posttraumatic nervous instability complicates all types of head injury, mild and severe. Once established, it may persist for months or even years, and it tends to resist all varieties of treatment. Eventually, the symptoms lessen. Strangely, this syndrome is almost unknown in children. Characteristic also is the augmentation of both the duration and intensity of this syndrome by problems with compensation and litigation, suggesting a psychologic factor. In countries where these matters are a less prominent part of the social fabric, the occurrence of posttraumatic syndrome is far less frequent. In respect to the syndrome of posttraumatic nervous instability, the constitution of the patient appears to be important. Stable, athletic, tough-fibered individuals take a concussive injury in stride, while the sensitive, nervous, complaining types may be so overwhelmed by such an accident that they are unable to expel it from their minds. Environmental stress assumes importance as well, for if too much is demanded of the patient soon after injury, irritability, insomnia, and anxiety are enhanced. In this connection, an interesting experiment has been conducted by [Mittenberg and colleagues](#). A group of subjects with no personal experience or knowledge of head injury were asked to select from a list those symptoms that they would expect after a concussive head injury. They chose a cluster of symptoms virtually identical to that of the postconcussion syndrome.

An approach to such patients is given further on, in the section on treatment under “Patients with Only Transient Unconsciousness.”

Other Posttraumatic Cognitive and Psychiatric Disorders

In all patients with cerebral concussive injury, there remains a gap in memory (traumatic amnesia) spanning a variable period from before the accident to some point following it. This gap is permanent and is filled in only by what the patient is told. In addition, as stated in the introduction to this section, some degree of impairment of higher cortical function may persist for weeks (or be permanent) after moderate to severe head injuries, even after the patient has reached the stage of forming continuous memories. During the period of deranged mentation, the memory disorder is the most prominent feature, so that the state resembles the alcoholic form of the Korsakoff amnesic state. It has been repeatedly asserted that this amnesic state is a constant feature of every prolonged traumatic mental disorder, but to the authors it reflects in part the ease with which memory can be tested. With more careful testing, other cognitive disorders are evident. Concussed patients, during the period of posttraumatic amnesia, rarely confabulate and usually have an impaired ability to register events and information, an abnormality not ordinarily observed in patients entering the chronic phases of Korsakoff psychosis. Apart from disorientation in place and time, the head-injured patient also shows defects in attention, distractibility, perseveration, and an inability to synthesize perceptual data. Judgment is impaired, sometimes severely. A perseverative tendency interferes with both action and thought.

As a general rule, the lower the score on the Glasgow Coma Scale ([Table 35-1](#)) and the longer the posttraumatic gap in the formation of memories (anterograde amnesia), the more likely the patient is to suffer permanent cognitive and personality changes. Abnormalities in these spheres were found in 12 percent of head-injured patients who had been in coma for longer than 24 h ([Sazbon et al](#)). If respiration and motor function were normal (except for early decorticate posturing) and there was no extraneural trauma, 94 percent of the patients recovered. According to Jennett and Bond, patients with good recovery achieved their maximum degree of improvement within 6 months. Others have found that detailed and repeated psychologic testing over a prolonged period, even in patients with relatively minor cerebral injuries, discloses measurable improvement for as long as 12 to 18 months.

There are other mental and behavioral abnormalities of a more subtle type that remain as sequelae to cerebral injury. As the stage of posttraumatic dementia recedes, the patient may find it impossible to work or to adjust to the family situation. Such patients continue to be abnormally abrupt, argumentative, stubborn, opinionated, and suspicious. Unlike the traumatic mental disorder described above, in which there is a certain uniformity, these traits vary with the patient's age, constitution, past experience, and the environmental stresses to which he is subjected. Extremes of age are important. The most prominent behavioral abnormality in children, described by [Bowman et al](#) is a change in character. They become impulsive, heedless of the consequences of their actions, and lacking in moral sense—much like those who had recovered from encephalitis lethargica. Some adolescents or young adults show the general lack of inhibition and impulsivity that one associates with frontal lobe disease. In the older person it is the impairment of intellectual functions that assumes prominence.

The tendency is for all such symptoms to subside slowly though not always completely, even in those in whom an accident has provoked a frank outburst of psychosis (as may happen to a manic-depressive, paranoid schizophrenic, or neurotic patient). These forms of “traumatic insanity” were carefully analyzed for the first time by Adolf Meyer.

Hysterical symptoms that develop after head injury appear to be more common than those following injury to other parts of the body. These symptoms are discussed in [Chap. 56](#).

TREATMENT

Patients with Only Transient Unconsciousness

Patients with an uncomplicated concussive injury who have already regained consciousness by the time they are seen in a hospital pose few difficulties in management. They should not be discharged until the appropriate examinations (CT scans, skull films, etc.) have been made and the results prove to be negative. Also, the patient should not be released until the capacity for consecutive memories has been regained and arrangements have been made for observation by the family of signs of possible though unlikely delayed complications (subdural and epidural hemorrhage, intracerebral bleeding, and edema).

The patients with persistent complaints of headache, dizziness, and nervousness, the syndrome that we have designated as *posttraumatic nervous instability*, are the

most difficult to manage. Three subgroups of this latter syndrome can be discerned. *In the first group*, the accident has provoked anxiety or an anxious depression. Compensation factors loom large in this group, especially for the patient whose circumstances are marginal and who is uncertain of a job and must care for dependents. Such a person is often willing to persist in illness, even if compensated at a level considerably below his earning capacity, if it provides a modicum of security. Obviously, we are often dealing here with matters that have little to do with the purely physical factors involved in cerebral trauma. The *second group* consists of patients in whom the *premorbid personality* was of a neurotic or depressive type. The injury to the brain is but one more factor in decompensating a tenuous social and occupational adjustment. The *third and smallest number of patients*, obviously the more severely injured, are found, upon close examination, to be *still suffering from a personality change and subtle impairments of cognitive function*, i.e., traumatic psychosis or dementia. The anxiety and depression reflect an awareness of their inability to cope with environmental stress.

A treatment program must be planned in accordance with the basic problem. If there is mainly an anxious depression, antidepressants—such as fluoxetine, paroxetine, or a tricyclic—are often useful. Simple analgesics, such as aspirin or acetaminophen or nonsteroidal anti-inflammatory drugs, should be prescribed for the headache. Litigation should be settled as soon as possible. To delay settlement usually works to the disadvantage of the patient. Long periods of observation, repetition of a multitude of tests, and waiting only reinforce the patient's worries and fears and reduce the motivation to return to work.

Severe Head Injury

If the physician arrives at the scene of the accident and finds an unconscious patient, a quick examination should be made before the patient is moved. First it must be determined whether the patient is breathing and has a clear airway and obtainable pulse and blood pressure, and whether there is dangerous hemorrhage from a scalp laceration or injured viscera. Severe head injuries that arrest respiration are soon followed by cessation of cardiac function. Injuries of this magnitude are often fatal; if resuscitative measures do not restore and sustain cardiopulmonary function within 4 to 5 min, the brain is usually irreparably damaged. The likelihood of a cervical fracture-dislocation, which is occasionally associated with head injury, is the reason for taking the precautions, outlined on page 1300, in moving the patient. It is best to assume that all such patients have had a neck injury and immobilize the cervical spine. Bleeding from the scalp can usually be controlled by a pressure bandage unless an artery is divided, and then a suture becomes necessary. Resuscitative measures (artificial respiration and cardiac compression) should be continued until they are taken over by ambulance personnel.

In the hospital the first step is to clear the airway and ensure adequate ventilation by endotracheal intubation if necessary. A careful search for other injuries must be made, particularly of the abdomen, chest, spine, and long bones. Although the hypotension that follows some injuries is a vasodepressor response and usually comes under control without pressor drugs, a large, unimpeded intravenous line should be inserted. Persistent hypotension due to head injury alone is an uncommon occurrence and should always raise the suspicion of a ruptured viscus or thoracic or abdominal internal bleeding, extensive fractures, or trauma to the cervical cord. The profound effects of sustained hypotension on outcome are commented upon below. Hypertension is a more common finding immediately after severe head injury (see further on). Initially, infused fluid should be normal saline, avoiding the administration of excessive free water because of its adverse effect on brain edema. Cervical spine films and a cranial CT scan should be obtained en route to the intensive care unit once vital functions are stable. If films of the cervical spine are negative, there is no longer a need to immobilize the neck.

A rapid survey can now be made, with attention to the depth of coma, size of the pupils and their reaction to light, ocular movements, corneal reflexes, facial movements during grimace, swallowing, vocalization, gag reflexes, muscle tone and movements of the limbs, predominant postures, reactions to pinch, and reflexes. Bogginess of the temporal or postauricular area (Battle sign), bleeding from the nose or ear, and extensive conjunctival edema and hemorrhage are useful signs of an underlying basal skull fracture. However, it should be remembered that rupture of an eardrum or a blow to the nose may also cause bleeding from these parts. Fracture of the orbital bones may displace the eye, with resulting strabismus; fracture of the jaw results in malocclusion and discomfort on attempting to open the mouth. If urine is retained and the bladder is distended, a catheter should be inserted and kept there. Temperature, pulse, respiration, blood pressure, and state of consciousness should be checked and charted every hour.

The *Glasgow Coma Scale*, mentioned above, provides a practical means by which the state of impaired consciousness can be evaluated at frequent intervals ([Table 35-1](#)), but it should not be considered a substitute for a more complete neurologic examination. It registers three aspects of neurologic functions: (1) eye opening (spontaneously, in response to command, and in response to pain); (2) verbal responsiveness (in terms of orientation, confusion, inappropriateness, and incomprehensibility); (3) motor responsiveness (to command, to a localized stimulus, flexion and extension responses to pressure on the limb). This scale requires little training of ward personnel. It is useful in following the course and predicting the outcome of severe head injuries (a score of less than 8 is associated with a poor prognosis). A deteriorating scale dictates a change in management.

CT scanning is of central importance at this juncture. A sizable epidural, subdural, or intracerebral blood clot is an indication for immediate surgery. The presence of contusions, brain edema, and displacement of central structures calls for measures to monitor progression of these lesions and to control intracranial pressure. These measures are best carried out in a critical care unit.

Management of Raised Intracranial Pressure It is the practice in some hospitals to insert one of several available devices that permits continuous recording of intracranial pressure (ICP) after moderate and severe head injury ([Narayan et al](#)). Pressure measurements through a lumbar puncture needle do not accurately reflect the ICP and increase the risk of a cerebellar or temporal lobe herniation. Nor do the neurologic signs that constitute the Glasgow Coma Scale reflect the pressure in the cranium. The arguments for and against monitoring the ICP have been addressed earlier (page 660). Our impression is that, in comatose patients, at a minimum, monitoring the ICP prevents errors in fluid administration and refines other details of management, including the appropriate use of osmotic diuretics and the correct level of hyperventilation. In these respects, monitoring can be helpful. However, there are few critical data to support the routine use of ICP monitoring; certainly the patient who is only drowsy or shows only minimal mass effect on CT scanning is not likely to benefit. In the absence of data to guide the decision regarding the insertion of these devices, we favor their use to guide therapy and warn of impending deterioration from brain edema or hemorrhage. The current generation of ICP monitors employs fiberoptic strain gauges that can be inserted directly into the cerebral cortex without apparent damage. While the risk of infection is low, prolonged use may be complicated by bacterial meningitis.

The first step in lowering high ICP is to control the secondary factors that are known to raise the pressure, such as hypoxia, hypercarbia, hyperthermia, awkward head positions, and high mean airway pressures ([Ropper](#)). If the intracranial pressure exceeds 15 to 20 mmHg, several measures can be instituted, such as inducing hypocarbia by controlled ventilation (maintaining P_{CO_2} at 28 to 33 mmHg) and by hyperosmolar dehydration (0.25 to 1.0 g of 20% mannitol every 3 to 6 h or 0.75 to 1 mg/kg of furosemide) to maintain serum sodium above 138 meq/L and osmolality at 290 to 300 mosmol/L. Even if ICP monitoring is not utilized, an attempt should be made to maintain this level of osmolality for the first days if contusion and brain swelling are detected on the CT scan. Elevations in osmolality that are due to excessive concentrations of solutes such as glucose are not useful in reducing intracranial volume because they do not provide a water gradient across the cerebral vasculature. For this reason, the measurement of serum sodium is in some ways a more accurate reflection of free water depletion. An initial sodium level of 136 to 141 meq/L is adequate. Intravenous fluids with free water should be avoided so as not to intensify cerebral edema. This poses a particular danger in children who, because of inappropriate secretion of antidiuretic hormone, easily develop water intoxication. With this exception, however, restriction of the overall volume of fluid is less of a concern than effecting a reduction in free water. Fluids such as 5% dextrose in water, 0.5% saline, and 5% dextrose in 0.5% saline are therefore avoided; lactated Ringer's solution is permissible but normal saline, with or without added dextrose, is ideal.

Hyperventilation is effective in reducing ICP for only a limited time since the pH of the spinal fluid equilibrates over hours and returns cerebral blood volume to its previous level. A single-step reduction in P_{CO_2} typically lowers ICP for approximately 20 to 40 min. In a few cases the effect may persist for hours. Attempts to prolong the effect of hypocarbia and alkalosis of the spinal fluid by the administration of ammonium buffers have met with mixed success. It has even been suggested that hyperventilation may be harmful to some head-injured patients, but the risk, if any, appears to be minimal.

If the ICP continues to rise and brain swelling to progress despite these measures, the outlook for survival is bleak. Hypothermia and barbiturate anesthesia to reduce ICP have been used, but relatively few patients respond to such measures. A randomized controlled trial of cooling patients with severe closed head injury (Glasgow Coma Scale scores of 3 to 7) to 33°C for 24 hours appeared to hasten neurologic recovery and may have modestly improved outcome ([Marion et al](#)). Barbiturates, while they lower ICP, may lower the blood pressure as well, which worsens the situation, though Marshall and coworkers claim a high rate of good survival even in cases where the ICP exceeded 40 mmHg. The more definitive randomized study by [Eisenberg](#) and associates showed no benefit from barbiturate anesthesia. Several large controlled studies have established that the administration of high-dose steroids does not significantly affect the clinical outcome of severe head injuries ([Gudeman et al](#); [Dearden et al](#); [Braakman et al](#); [Saul et al](#)). The use of decompression craniectomy in cases of intractable brain swelling is commented upon below.

The management of posttraumatic systemic hypertension can be a difficult problem. Immediately after head injury there is a sympathoadrenal response and elevation of blood pressure which recede spontaneously in a matter of a few hours or days. Unless the blood pressure elevation is severe (greater than 180/95 mmHg), it can

be disregarded in the early stages. In animal experiments, it has been found that severe hypertension leads to increased perfusion of the brain and an augmentation of the edema surrounding contusions and hemorrhages. As mentioned earlier, edema is the main element in the genesis of brain swelling and raised ICP in head-injured patients ([Marmarou et al](#)). This sequence reflects a failure of autoregulatory vascular mechanisms, with resulting transudative edema in damaged areas of the brain. The control of high blood pressure must be balanced against the risk of reducing cerebral perfusion pressure and the observation that even a brief period of mild hypotension may provoke a cycle of cerebral vasodilation, increased cerebral blood volume, and elevated ICP in the form of a plateau wave ([Rosner and Becker](#)). Data such as these emphasize the need for immediate and vigorous management of hypotension in severely head-injured patients. Chestnut et al, in a study of patients from the Traumatic Coma Data Bank, found that sustained early hypotension (systolic BP<90 mmHg) was associated with a doubling of mortality. If shock was present on admission to the emergency ward, the mortality was 65 percent.

Since most therapies for elevated ICP dehydrate the patient or reduce cardiac filling pressures, leading to hypotension, a middle course, of avoiding both severe hypertension and hypotension, seems the best compromise. In lowering high levels of blood pressure, diuretics, beta-adrenergic blocking agents, or angiotensin converting enzyme inhibitors should be used, rather than agents that dilate the cerebral vasculature (nitroglycerin and nitroprusside, hydralazine, and some of the calcium channel blockers). Hypotension should be corrected by vasopressor agents such as neosynephrine. The precise level of blood pressure that requires treatment must be judged in the context of the ICP and the presence of plateau waves (the goal being to maintain normal cerebral perfusion), the patient's previous blood pressure level, and evidence of end-organ failure such as cardiac ischemia.

General Medical Measures If coma persists for more than 48 h, a nasogastric tube should be passed and fluids and nutrition given by this route. Agents that reduce gastric acid production—or the equivalent, antacids by stomach tube to keep gastric acidity at a pH above 3.5—are of value in preventing gastric hemorrhage. The prophylactic use of anticonvulsant drugs, as discussed earlier under “Posttraumatic Epilepsy,” is not generally favored. Only if there has been a seizure are conventional anticonvulsants given.

Restlessness is controlled by diazepam or a similar sedative, but only if careful nursing fails to quiet the patient and provide sleep for a few hours at a time. Haloperidol is usually avoided in the acute stage. Fever is counteracted by antipyretics such as acetaminophen, and, if necessary, by a cooling blanket.

Surgical Measures The need for surgical intervention during the acute posttraumatic period is decided by two factors: the clinical status of the patient and CT scanning. The presence of a subdural or epidural clot that is causing a shift of central brain structures calls for its immediate evacuation. The approach to subdural hematomas has been discussed earlier in the chapter. Should the elevated ICP not respond to this procedure or to the standard osmotic agents and other medical measures outlined above, or should the condition of the patient and vital signs then begin to deteriorate (pulse rising, temperature rising or falling below normal, state of consciousness worsening, hemiplegia more obvious, plantar reflexes more clearly extensor), a renewed search must be undertaken for a late-occurring cerebral mass. Usually, in these clinical circumstances, CT scanning will disclose an epidural, subdural, or intracerebral hematoma, marked cerebral edema, and a lateral shift of central cerebral structures. *If death or severe disability is to be avoided, operation in these cases must be undertaken before the advanced signs of brainstem compression—decerebrate or decorticate posturing, hypertension, bradycardia—have appeared.*

The use of *decompressive craniectomy* in patients with progressive and intractable traumatic brain swelling has been a subject of renewed interest in recent years, after having been practically abandoned several decades ago. Guerra and colleagues have reported on 57 such patients, mostly young adults, who underwent wide frontotemporal craniectomy, unilateral in 31 and bilateral in 26. Of these, 11 patients died, 5 remained in a persistent vegetative state, and 6 survived in a severely damaged condition; however, 33 patients (58 percent) attained surprisingly good states of rehabilitation. The authors were of the opinion that these results represented a significant improvement over the expected outcome in this particular category of patients. Similar results in children have been reported by [Polin et al](#).

The treatment of other problems attendant upon protracted coma has been outlined in [Chap. 17](#). Every patient presents certain unique problems that must be dealt with individually.

PROGNOSIS

In respect to severe head injury, as has been intimated, the outcome is particularly discouraging. In the large European Brain Injury Consortium survey, comprising 10,005 adult patients, the injury proved fatal in 31 percent; 3 percent were left in a persistent vegetative state, and 16 percent remained severely neurologically disabled ([Murray et al](#)). Data from the Traumatic Coma Data Bank are comparable ([Marshall et al](#)). The signs of focal brain disease, whether due to closed head injuries or to open and penetrating ones, tend always to ameliorate as the months pass. A hemiplegia is often reduced to a minimal hemiparesis or to an ineptitude of voluntary motor function with exaggerated reflexes and an equivocal Babinski sign on that side, and an aphasia is gradually transformed into a stuttering or hesitant paraphasia or dysnomia that is not disabling except to a professional person, speaker, or writer. Many of the signs of brainstem disease (cranial nerve dysfunction and ataxia) improve also, usually within the first 6 months after injury ([Jennett and Bond](#)), and often to a surprising extent. Most patients who had been in coma for many hours or days, i.e., those with severe brain injuries, are left with memory impairment and other cognitive defects and with personality changes. These may be the only lasting sequelae. According to Jennett and Bond, these mental and personality changes are a greater handicap than focal neurologic ones as far as social adjustment is concerned. In open head wounds and penetrating brain injuries, Grafman and coworkers found that the magnitude of tissue loss and location of the lesion were the main factors affecting the outcome.

The prognosis of head injury is influenced by several other factors. The *age of the patient* is the most important of these ([Vollmer et al](#)). Increasing age reduces the chances of survival and of good recovery. Older patients often remain disabled, especially when compensation is involved. Young and middle-aged ones do better, particularly if they are not entitled to compensation. Russell has pointed out that the severity of the injury as measured by the duration of *traumatic amnesia* is a useful prognostic index. Of patients with a period of amnesia lasting less than 1 h, 95 percent were back at work within 2 months; if the amnesia lasted longer than 24 h, only 80 percent had returned to work within 6 months. However, about 60 percent of the patients in his very large series still had symptoms at the end of 2 months, and 40 percent at the end of 18 months. Of the most severely injured (those comatose for several days), many remained permanently disabled. However, the degree of recovery was often better than one had expected; the motor impairment, aphasia, and dementia tended to lessen and sometimes cleared. Improvement could continue over a period of 3 or more years. Children seemed to recover more completely than adults.

Treatment

Acute Disseminated Encephalomyelitis (ADEM)

Postinfectious, Postexanthem, Postvaccinal Encephalomyelitis

Acute Necrotizing Hemorrhagic Encephalomyelitis (Acute Hemorrhagic Leukoencephalitis of Weston Hurst)

Chapter References

It has long been the practice to set apart a group of diseases of the brain and spinal cord in which destruction of myelin (demyelination) is a prominent feature. To define these diseases precisely is difficult, for the simple reason that there is probably no disease in which myelin destruction is the exclusive pathologic change. The idea of a demyelinative disease is, more or less, an abstraction that serves primarily to focus attention on one of the more striking and distinctive features of the pathologic process.

The commonly accepted pathologic criteria of a demyelinative disease are (1) destruction of the myelin sheaths of nerve fibers; (2) *relative* sparing of the other elements of nervous tissue, i.e., of axis cylinders, nerve cells, and supporting structures; (3) infiltration of inflammatory cells in a perivascular distribution; (4) a particular distribution of lesions, often perivenous and primarily in white matter, either in multiple small disseminated foci or in larger foci spreading from one or more centers; and (5) a relative lack of wallerian, or secondary, degeneration of fiber tracts (an expression of the relative integrity of the axis cylinders in the lesions).

A classification of the demyelinative diseases is presented in [Table 36-1](#). The diseases included in this classification conform approximately to the criteria enumerated above. Like all classifications that are not based on etiology, this one has its shortcomings in that it is somewhat arbitrary and inconsistent. In some of the diseases here classified as demyelinative, notably Schilder disease and necrotizing hemorrhagic leukoencephalitis and even multiple sclerosis, there can be a severe degree of damage to axis cylinders as well as to myelin. Contrariwise, a number of diseases in which demyelination is a prominent feature are not included. In some cases of anoxic encephalopathy, for example, the myelin sheaths of the radiating nerve fibers in the deep layers of the cerebral cortex or in ill-defined patches in the convolutional and central white matter are destroyed, while most of the axis cylinders are spared. A relatively selective degeneration of myelin may also occur in some small ischemic foci due to vascular occlusion or in larger confluent areas as in Binswanger disease (see [Chap. 34](#)). In subacute combined degeneration (SCD) of the spinal cord associated with pernicious anemia and in tropical spastic paraparesis (TSP), a demyelinating spinal cord disease, myelin may be affected earlier and to a greater extent than axis cylinders; the same is true of progressive multifocal leukoencephalopathy (PML), adrenoleukodystrophy (ADL), central pontine myelinolysis, and Marchiafava-Bignami disease. Some of these disorders and several others are no longer classified as demyelinative because their etiology has become known. PML is a viral infection of oligodendrocytes in immune-deficient subjects, ADL is a hereditary disease related to a defect in peroxisomal enzymes, SCD is due to vitamin B₁₂ deficiency, and TSP is caused by a retrovirus, for which reasons these disorders are more appropriately included with the viral and nutritional diseases. Other diseases are not categorized as demyelinative because they lack the characteristic perivascular inflammatory changes and exhibit pathologic features that are judged to be more fundamental than the demyelination. Also, for reasons that will become clear in subsequent discussion, the chronic progressive leukodystrophies of childhood and adolescence (e.g., globoid body, metachromatic, and adrenal leukodystrophies), while clearly diseases of myelin, are set apart because of their unique genetic and morphologic features and are discussed in [Chap. 37](#). Occupying an uncertain place in this nosology are demyelinative lesions associated with connective tissue diseases or merely with autoantibodies directed against DNA or phospholipids. The central nervous system (CNS) lesions may be multiple and cannot easily be distinguished radiologically from multiple sclerosis (MS), but, as noted further on, their nature is uncertain and some are due to vasculitis. Excluded from discussion in this chapter are demyelinative diseases of the peripheral nerves, although they share a number of pathologic features with demyelinating diseases of the CNS; they are described in [Chap. 46](#).

I. Multiple sclerosis (disseminated sclerosis)
A. Chronic relapsing encephalomyelopathic form
B. Acute multiple sclerosis
C. Diffuse cerebral sclerosis (encephalitis periaxialis diffusa) of Schilder and concentric sclerosis of Baló
II. Neuromyelitis optica (Devic)
III. Acute disseminated encephalomyelitis
A. Following measles, chickenpox, smallpox, mumps, rubella, influenza, and other viral and some bacterial infections (<i>Mycoplasma</i> , <i>Rickettsia</i> , etc.)
B. Following rabies or smallpox and rarely other types of vaccination (postvaccinal)
IV. Acute and subacute necrotizing hemorrhagic encephalitis
A. Acute encephalopathic form (hemorrhagic leukoencephalitis of Hurst)
B. Subacute necrotic myelopathy

Table 36-1 Classification of the demyelinative diseases

In the language of neurology, therefore, the term *demyelination* has acquired a special meaning; if it is to retain its value, it should be used in the restricted sense indicated above and not as a synonym for complete degeneration of nerve fibers or necrosis of white matter, even though the lesions may look alike in a section stained for myelin.

MULTIPLE SCLEROSIS

Multiple sclerosis, referred to by the British as *disseminated sclerosis* and by the French as *sclerose en plaques*, is among the most venerable of neurologic diseases and one of the most important by virtue of its frequency, chronicity, and tendency to attack young adults. It is characterized clinically by episodes of focal disorder of the optic nerves, spinal cord, and brain, which remit to a varying extent and recur over a period of many years. The neurologic manifestations are protean, being determined by the varied location and extent of the demyelinative foci; nevertheless, the lesions have a predilection for certain portions of the CNS, resulting in complexes of symptoms and signs and radiologic appearances that can often be recognized as characteristic of MS.

Classic features include motor weakness, paraparesis, paresthesias, impaired vision, diplopia, nystagmus, dysarthria, intention tremor, ataxia, impairment of deep sensation, and bladder dysfunction. Diagnosis may be uncertain at the onset and in the early years of the disease, when symptoms and signs point to a lesion in only one locus of the nervous system. Later, as the disease recurs and disseminates throughout the cerebrospinal axis, diagnostic accuracy approaches 100 percent. A long period of latency (1 to 10 years or longer) between a minor initial symptom, which may not even come to medical attention, and the subsequent development of more characteristic symptoms and signs may delay the diagnosis. In most cases the initial manifestations improve partially or completely, to be followed after a variable interval by the recurrence of the same abnormalities or the appearance of new ones in other parts of the nervous system. In as many as half the patients, the disease takes the form of an intermittently progressive illness and sometimes of a steadily progressive one, especially in patients more than 40 years of age. A rule

that has guided clinicians for many years is that the diagnosis of MS is not secure unless there is a history of remission and relapse and evidence on examination of more than one discrete lesion of the CNS. The advent of certain ancillary procedures—notably evoked potentials and magnetic resonance imaging (MRI)—and their capacity to identify clinically inapparent lesions has obviated the exclusive dependence on clinical criteria for the diagnosis.

Pathologic Findings

Before being sectioned, the brain generally shows no evidence of disease, but the surface of the spinal cord may appear and feel uneven. Sectioning of the brain and cord discloses numerous scattered patches where the tissue is slightly depressed below the cut surface and stands out from the surrounding white matter by virtue of its pink-gray color (due to loss of myelin). The lesions may vary in diameter from less than a millimeter to several centimeters; they affect principally the white matter of the brain and spinal cord and do not extend beyond the root entry zones of the cranial and spinal nerves. It is because of their sharp delineation that they were called *plaques* by French pathologists.

The topography of the lesions is noteworthy. A periventricular localization is characteristic, but only where subependymal veins line the ventricles (mainly adjacent to the bodies and atria of the lateral ventricles). Other favored structures are the optic nerves and chiasm (but rarely the optic tracts) and the spinal cord, where pial veins lie next to the white matter (see [Fig. 36-1](#) and [Fig. 36-2](#); see also page 969 on “[MRI in MS](#)”). The lesions are distributed randomly throughout the brainstem, spinal cord, and cerebellar peduncles without reference to particular systems of fibers. In the cerebral cortex and central nuclear and spinal structures, the lesions destroy myelin sheaths but leave the nerve cells essentially intact.

Figure 36-1 Multiple sclerosis. T2-weighted MR images demonstrating multiple plaques in the periventricular white matter (left) and cervical spinal cord (right).

Figure 36-2 Multiple sclerosis. Gadolinium-enhanced MRI in a 36-year-old male with subacute evolution of diminished visual acuity. Enhancing plaques are seen in the optic chiasm and floor of the lateral ventricle.

The histologic appearance of the lesion depends on its age. Relatively recent lesions show a partial or complete destruction and loss of myelin throughout a zone formed by the confluence of many small, predominantly perivenous foci; the axis cylinders are relatively spared. There is a variable but slight degeneration of oligodendroglia, a neuroglial (astrocytic) reaction, and perivascular and para-adventitial infiltration with mononuclear cells and lymphocytes. Later, large numbers of microglial phagocytes (macrophages) infiltrate the lesions, and astrocytes in and around the lesions increase in number and size. Long-standing lesions, on the other hand, are composed of thickly matted, relatively acellular fibroglial tissue, with only occasional perivascular lymphocytes and macrophages; in such lesions, a few intact axis cylinders may still be found. Sparing of axis cylinders (axons) prevents wallerian degeneration. However, in old lesions with interruption of axons, there may be descending and ascending degeneration of long fiber tracts in the spinal cord. Partial remyelination is believed to take place on undamaged axons and to account for the partially demyelinated “shadow patches” ([Prineas and Connell](#)). Exceptionally, a few of the older lesions undergo cavitation, indicating that the disease process has affected not only myelin and axons but also supporting tissues and blood vessels as well. All gradations of histopathologic change between these two extremes may be found in lesions of diverse size, shape, and age, consistent with the extended clinical course.

Etiology and Epidemiology

Cruveilhier (circa 1835), in his original description of the disease, attributed it to suppression of sweat, and since that time there has been endless speculation about the etiology. Many of the early theories appear ludicrous in the light of present-day concepts, and others are of only historical interest. There is no point in enumerating them here; complete accounts are to be found in the reviews of DeJong (1970), Prineas (1970), R. T. Johnson (1978), and McDonald (1986).

Although the precise cause of MS remains undetermined, a number of epidemiologic facts have been clearly established and will eventually have to be incorporated in any etiologic hypothesis. The disease has a prevalence of less than 1 per 100,000 in equatorial areas; 6 to 14 per 100,000 in the southern United States and southern Europe; and 30 to 80 per 100,000 in Canada, northern Europe, and the northern United States. A less well defined gradient exists in the Southern Hemisphere. Kurland's studies indicate that there is a threefold increase in prevalence and a fivefold gradient in mortality rate between New Orleans (30 degrees north latitude) on the one hand, and Boston (42 degrees north) and Winnipeg (50 degrees north) on the other. In Japan there is a similar though less distinct geographic gradient; however, the prevalence of MS there is much lower than in corresponding latitudes of North America and northern Europe.

The increasing risk of developing MS with increasing latitude has been confirmed by [Kurtzke](#) and associates, who studied a series of unprecedented size (5305 undoubted cases of MS and matched controls). Their study showed that in the United States, African Americans are at lower risk than whites at all latitudes, but both races show the same south-to-north gradient in risk, indicating the importance of an environmental factor regardless of race. Supporting this view are the descriptions, by [Kurtzke and Hyllested](#), of an “epidemic” of MS in the Faroe Islands of the North Atlantic. They found a much higher than expected incidence of the disease, occurring as three separate outbreaks of decreasing extent between the years 1943 and 1973. It is their contention that the disease was introduced by British troops who occupied the islands in large numbers in the years immediately preceding the outbreak. Kurtzke and colleagues have also described a similar postwar epidemic in Iceland.

Several studies indicate that persons who migrate from a high-risk to a low-risk zone carry with them at least part of the risk of their country of origin, even though the disease may not become apparent until 20 years after migration. Such a pattern has been demonstrated in both South Africa and Israel. Dean determined that the prevalence in native-born white South Africans was 3 to 11 per 100,000, whereas the rate in immigrants from northern Europe was about 50 per 100,000, only slightly less than in the nonimmigrating natives of those countries. The data of Dean and Kurtzke indicate further that in persons who had immigrated before the age of 15, the risk was similar to that of native-born South Africans; whereas in persons who had immigrated after that age, the risk was similar to that of their birthplace. Alter and colleagues found that in the descendants of European immigrants born in Israel, the risk of MS was low, similar to that of other native-born Israelis, whereas among recent immigrants the incidence in each national group approached that of the land of birth. Again, the critical age of immigration appeared to be about 15

years. These epidemiologic studies and others have shown that MS is associated with particular localities rather than with a particular ethnic group in those localities and emphasize the importance of environmental factors in the genesis of the disease.

Also, a familial aggregation of MS is now well established. About 15 percent of MS patients have an affected relative, with the highest risk of concurrence (5 percent) being observed in the patient's siblings ([Ebers, 1983](#)). In a large population-based study carried out in British Columbia by [Sadovnick and colleagues](#), it was found that almost 20 percent of index cases had an affected relative, again with the highest risk in siblings. In a subsequent study, Sadovnick and colleagues studied the heritability of MS by comparing the risk of disease in the half-sibs (one biologic parent in common) of affected individuals with the risk in full sibs. They found that the risk for full sibs was two to three times greater than for half-sibs and they interpreted these results to mean that the difference is largely genetic.

The case for heritability is supported also by studies of twins in whom one of each pair is known to have MS. In the most careful of these studies ([Ebers et al](#)), the diagnosis was verified in 12 of 35 pairs of monozygotic twins (34 percent) and in only 2 of 49 pairs of dizygotic twins (4 percent). Notable also was the observation that in two additional sets of monozygotic twins who were clinically normal, lesions were detected by MRI. The concordance rate in dizygotic pairs is similar to that in nontwin siblings. However, within families with more than one affected member, no consistent pattern of mendelian inheritance has emerged. Of course, one must not assume that all diseases with an increased familial incidence are hereditary, for instances of the same condition in several members of a family may simply reflect an exposure to a common environmental agent. Paralytic poliomyelitis, for example, was about eight times more common in immediate family members than in the population at large.

Further suggestive of a genetic factor in the causation of MS is the finding that certain histocompatibility antigens (HLAs) are more frequent in patients with multiple sclerosis than in control subjects. The strongest association is with the DR locus on the sixth chromosome. Other HLAs that are overrepresented in MS (HLA-DR2 and, to a lesser extent, -DR3, -B7, and -A3) are thought to be markers for an MS “susceptibility gene”—possibly an immune response gene. The presence of one of these markers is said to increase the risk that an individual will develop MS by a factor of 3 to 5. These antigens may indeed prove to be related to the frequency of the disease, but their presence is not invariable and their exact role is far from clear (see [Compston](#)).

The low conjugal incidence of MS supports the view that common exposure to this disease must occur early in life. In order to test this hypothesis, Schapira and coworkers determined the periods of common exposure (common habitation periods) in members of families with two or more cases. From this they calculated the mean common exposure to have happened before 14 years of age, with a latency of about 21 years—figures that are in general agreement with those derived from the migration studies quoted above.

The incidence of MS is two or three times higher in women than in men, but the significance of this fact is unclear. The incidence in children is very low; only 0.3 to 0.4 percent of all cases appear during the first decade. In an analysis of three childhood-onset cases, Hauser and colleagues found no phenotypic differences between childhood and adult cases. Beyond childhood, the risk of first developing symptoms of the disease rises steeply with age, reaching a peak at about 30 years, remaining high in the fourth decade, then falling off sharply and becoming low in the sixth decade. It has been pointed out that MS has a unimodal age-specific onset curve, similar to the age-specific onset curves of many infectious diseases.

About two-thirds of cases of MS have their onset between 20 and 40 years of age. Of the remainder, most cases begin before the age of 20; in a smaller number, the disease appears to develop in late adult life (late fifties and sixties). In the latter patients, early symptoms may have been forgotten or may never have declared themselves clinically (we have several times found the typical lesions of MS in autopsied individuals who had no history of neurologic illness). Gilbert and Sadler report five such cases and from their pathologic findings declare that the true incidence of MS may be three times higher than stated figures.

Several studies from northern Europe and Canada have suggested that the likelihood of developing MS is somewhat greater among rural than among urban dwellers; studies of American army personnel indicate the opposite ([Beebe et al](#)). A number of surveys in Great Britain have intimated that the disease is more frequent in the higher socioeconomic groups than in the lower ones. Yet in the United States, no clear relationship has been established to the poverty or social deprivations that are part of a low socioeconomic status. Numerous other environmental factors (surgical operations, trauma, anesthesia, exposure to household pets, mercury in silver amalgam fillings in teeth) have been proposed but are unsupported by firm evidence.

Pathogenesis

All these epidemiologic data point to a relationship between MS and some environmental factor that is encountered in childhood and, after years of latency, either evokes the disease or contributes to its causation. In recent years, speculation has grown that this factor is an infection, most often viral. A large body of indirect evidence has been marshaled in support of this idea, based on the demonstration, in patients with MS, of alterations in humoral and cell-mediated immunity to viral agents (see reviews of [R. T. Johnson](#), [Lampert](#), [K. P. Johnson](#) et al, [McFarlin and McFarland](#), and [Antel and Cashman](#)). However, to this day no virus (including all known members of the human retrovirus family) has been seen in or isolated from the tissues of patients with MS despite innumerable attempts to do so, and no satisfactory viral model of MS has been produced experimentally. Nevertheless, the fact that a retrovirus produces tropical spastic paraparesis (a demyelinating disease) and the experimental production of a demyelinating disease in transgenic mice that express a T-cell receptor for myelin basic protein (but not in mice that are kept in a sterile environment; Goverman et al) continue to spur the search for a viral causation of MS. Recently, the bacterial agent *Chlamydia pneumoniae* and herpesvirus type 6 have been similarly implicated by the finding of their genomic material in MS plaques, but the evidence for their direct participation in the disease is no more compelling than that for any other infectious agent.

If indeed the initial event in the genesis of MS is a viral or other infection of the nervous system, then some secondary factor must be operative in later life to activate the neurologic disease and cause exacerbations. The most popular view is that this secondary mechanism is an autoimmune reaction, attacking some components of myelin and, in its most intense form, destroying all tissue elements, including axons. Several lines of argument have been advanced in support of this view. One is to draw an analogy between the lesions of MS and those of disseminated encephalomyelitis, which is almost certainly an autoimmune disease of delayed hypersensitivity type (see further on). Another is that antibodies to specific myelin proteins—e.g., myelin basic protein (MBP)—have been found in both the serum and cerebrospinal fluid (CSF) of MS patients, and these antibodies, along with T cells that are reactive to MBP and to other myelin proteolipids, increase with disease activity; moreover, MBP cross-reacts to some extent with measles virus antibodies. The arguments that a chronic viral infection reactivates and perpetuates the disease are, however, less convincing than those proposing a role for viruses in the initiation of the process in susceptible individuals.

A possible way in which viral infections and autoimmune reactions in the nervous system might be linked to the abnormal expression of autoantigens on CNS cells has been suggested by [R. T. Johnson](#). He found that several different viruses (rubeola, rubella, varicella) could cause autoimmunization of T lymphocytes against myelin basic protein. This means that the T lymphocyte recognizes an identical structure in the virus and myelin sheath. Once the autoimmune process is initiated by a virus in childhood, it can later be reactivated by any of the common viral infections to which the individual is exposed, particularly in the higher northern and southern latitudes. This phenomenon of molecular mimicry (a shared antigen between the virus and CNS myelin or the oligodendrocyte) has been invoked as a mechanism in several diseases, notably in rheumatic fever, certain paraneoplastic diseases, and Guillain-Barré syndrome.

The role of humoral and cellular factors in the production of MS plaques is not fully understood. That the humoral immune system is involved is evident from the presence in the CSF of most patients of oligoclonal immune proteins, which are produced by B lymphocytes within the CNS. Sera from patients with MS (and some normal controls), when added to organotypic cultures of nervous system tissue from newborn mice in the presence of complement, can damage myelin, inhibit remyelination, and block axonal conduction. Antibodies to oligodendrocytes are present in the serum of up to 90 percent of patients in some studies, but far less in others.

In respect to cellular factors, the focus of attention in recent years has been on the pathogenetic role of T lymphocytes, which regulate humoral immune responses either as potentiators (T-helper cells) or as inhibitors (T-suppressor cells) of immunoglobulin production by the B lymphocytes. So-called helper (CD4+) T cells are found in abundance within MS plaques and surrounding venules (perivascular cuffing). It has been demonstrated that T-cell receptors respond to antigens presented by (major histocompatibility complex, or MHC) class II molecules on macrophages and astrocytes. This interaction is thought to stimulate T-cell proliferation and a cascade of related cellular events, including the activation of B cells and macrophages and the secretion of cytokines (one of which is interferon beta and another interferon gamma; see further on). These cellular events are accompanied by a breakdown of the blood-brain barrier and, if sufficiently intense, by destruction of oligodendrocytes and myelin (see review by [Ffrench-Constant](#)). These findings strongly support the concept of a T-cell-mediated autoimmune inflammatory reaction, at least as a mechanism for sustaining the inflammation. A reduction in the blood of suppressor T lymphocytes was originally thought to characterize clinical relapse but has proved to be an inconstant feature. However, a reduction in T cells, both helper and suppressor subsets, or an increase in helper-suppressor ratios, does appear to be associated with increasing disability in patients with MS.

Many immunologists subscribe to the notion that MS is a T-cell-mediated disease. The idea is supported by evidence that T cells initiate the lesions of experimental allergic encephalomyelitis (EAE), which is repeatedly invoked as the animal model of MS. Although the entry of autoreactive T cells into the CNS results in a perivascular inflammatory reaction, the relationship to the main feature of MS, demyelination, is unclear. Conceivably, intense T-cell stimulation is in itself sufficient to induce demyelination, but it is also possible that the primary target of the immune reaction is the oligodendrocyte itself or its myelin processes and that the T-cell infiltration is the result of the demyelination. Other investigators believe that an additional insult is required, as illustrated by the EAE animal model, in which myelin and an adjuvant immune stimulus of portions of the tubercle bacilli are required. But EAE may be an imperfect model; it is not a naturally occurring disease but one in which a demyelination of the CNS is induced in susceptible animals by immunization with autologous myelin antigens. In other words, the inducing antigen in EAE is well defined, whereas *the antigen in MS is not known*. Nor, in broader terms, is the autoimmune hypothesis of MS beyond challenge. It is noteworthy that the prevalence of other diseases of presumed autoimmune origin is no higher in MS patients than in the general population ([De Keyser](#)). Moreover, the course of MS has been altered only inconsistently and to a slight extent by the administration of any of the nonspecific immunosuppressive therapies ([Goodkin et al](#), 1992).

In summary, the immune mechanisms that are operative in the genesis of MS cannot as yet be specified.

Also worthy of comment is the relatively ineffective remyelination of the MS plaque. When remyelination occurs, thinly myelinated fibers are produced, creating areas of so-called shadow plaques. Histologic evidence suggests not only that some of the oligodendrocytes are destroyed in areas of active demyelination but also that the remaining ones have little ability to proliferate. Instead, there is an influx of oligodendroglial precursor cells, which mature into oligodendrocytes and provide the remaining axons with new myelin. Probably, the astrocytic hyperplasia in regions of damage and the persistent inflammatory response account for the inadequacy of the reparative process (see [Prineas et al](#)).

Physiologic Effects of Demyelination

The main physiologic effect of demyelination is to impede saltatory electrical conduction from one node of Ranvier, where sodium channels are concentrated, to the next node. The resulting failure of electrical transmission is thought to underlie most of the abnormalities of function resulting from demyelinating disease of both the central and peripheral nerve fibers. The delay in electrical conduction in the optic nerve (found by using pattern-shifting visual stimuli in MS patients with normal visual acuity and normal visual fields) raises a number of points about the pathophysiology of demyelination. When the demyelinative process is acute and reversible within a few days, the block in nerve fiber conduction is obviously physiologic rather than pathologic; in such a brief period, recovery is unlikely to have been due to remyelination. More likely, recovery is due to subsidence of the edema and acute inflammatory changes in and around the lesion. Remyelination probably does occur, as described above, but it is a slower process and partial at best, and its functional effects in the CNS are unknown. A slowing of optic nerve conduction, if it is present in an eye with normal vision, may account for the reduction in flicker fusion and in perception of multiple visual stimuli ([Halliday and McDonald](#)). It also explains one of the classic symptoms of optic neuritis—a reduction in the intensity (desaturation) of the color red. It is clear, however, that many of the plaques visualized on MRI are unaccompanied by corresponding symptoms; in some cases as well, there is no electro-physiologic abnormality, as tested with evoked responses. Either there has been remyelination in these plaques, sufficient to support clinical functioning, or, in the acute stage, the plaque may represent edema rather than demyelination.

Another classic feature of MS is the temporary induction, by heat or exercise, of symptoms such as unilateral visual blurring (the Uhthoff phenomenon) or tingling and weakness of a limb (the basis of the hot-tub test used in previous years). This has been shown experimentally to represent an extreme sensitivity of conduction in demyelinated nerve fibers to an elevation in temperature. A rise of only 0.5°C can block electrical transmission in some demyelinated fibers. Likewise, hyperventilation slows conduction of the visual evoked response, an effect that is rarely perceived by the patient. The remarkable sensitivity of demyelinated and remyelinated regions to subtle metabolic and environmental changes provides an explanation for the rapid onset of symptoms in some patients and the apparent fluctuations of MS that show no laboratory evidence of active inflammatory changes in the CNS. Smoking, fatigue, hyperventilation, and a rise in environmental temperature are all capable of briefly worsening neurologic functioning and are easily confused with relapses of disease.

Precipitating Factors

A variety of events occurring immediately before the initial symptoms or exacerbations of MS have been invoked as precipitating factors. The most common are infection, trauma, and pregnancy. However, in our view, none of these has been convincingly related to an increased risk of new attacks of MS, and there are no adequately controlled studies that would contradict this view. The incidence of respiratory or gastrointestinal viral infections that precede the onset or exacerbations of the disease varies greatly in different series, from 5 to 50 percent. The swine influenza vaccine, which was given to 45 million persons in the United States in late 1976, caused a slight increase in the incidence of Guillain-Barré disease but not of MS ([Kurland et al](#)). On the other hand, in an occasional individual an endogenous infection, such as labial or genital herpes, has regularly preceded an attack of MS.

The possible role of trauma in precipitating MS is more difficult to assess. McAlpine and Compston found that the incidence of trauma within a 3-month period preceding the onset of MS was slightly greater than in a random control group of hospital patients. Furthermore, there appeared to be a relationship between the site of the injury and the site of initial symptoms, particularly in patients who developed symptoms within a week of injury. We do not find this evidence convincing. Other forms of trauma (including lumbar puncture and general surgical procedures) that occur after the onset of the neurologic disorder have not been shown to have an adverse effect on the course of the illness. Matthews, who has extensive personal experience with survivors of penetrating head wounds, did not find a single instance of MS among them. One of the most meaningful prospective studies of the relation of physical injury to MS is that of Sibley and colleagues. They followed 170 MS patients and 134 controls for an average of 5 years, during which they recorded all (1407) instances of trauma and measured their effects on exacerbation rate and progression of the disease. With the possible exception of a case or two of electrical injury, there was no significant correlation between traumatic episodes and exacerbations.

Certain other epidemiologic data have a bearing on this subject. There are, in the United States, 250,000 to 350,000 cases of physician-diagnosed MS ([Anderson et al](#)). Also, a study from the National Center for Health Statistics has determined that trauma sufficiently severe to be recalled at a periodic health examination occurs in one-third of the population of the United States (some 83 million persons) each year. Moreover, MS patients suffer physical injuries two or three times more often than normal persons ([Sibley et al](#)). In light of these data, it is hardly surprising that a traumatic event and an exacerbation should sometimes coincide, quite by chance.

Clinical Manifestations

The conventional view of MS as a disease that strikes young people at a time when they are enjoying perfect health is not altogether correct. In some patients, the history discloses that fatigue, lack of energy, weight loss, and vague muscle and joint pains had been present for several weeks or months before the onset of neurologic symptoms. Nor is it generally appreciated that the neurologic disorder may have an acute, almost apoplectic onset. In fact, McAlpine and coworkers (1972), who analyzed the mode of onset in 219 patients, found that in about 20 percent the neurologic symptoms were fully developed in a matter of minutes, and in a similar number, in a matter of hours. In about 30 percent the symptoms evolved more slowly, over a period of a day or several days, and in another 20 percent more slowly still, over several weeks to months. In the remaining 10 percent the symptoms had an insidious onset and slow, steady, or intermittent progression over months and years. The relapsing-remitting pattern of disease is more likely to appear in patients who are less than 40 years of age. The inflammatory process of MS affects no organ system except the CNS.

Early Symptoms and Signs Weakness or numbness, sometimes both, in one or more limbs is the initial symptom in about half the patients. Symptoms of tingling of the extremities and tight band-like sensations around the trunk or limbs are commonly associated and are probably the result of involvement of the posterior columns of the spinal cord. The resulting clinical syndromes vary from a mere dragging or poor control of one or both legs to a spastic or ataxic paraparesis. The tendon reflexes are retained and later become hyperactive with extensor plantar reflexes; disappearance of the abdominal reflexes and varying degrees of deep and superficial sensory loss may be associated. It is a useful adage that the patient with MS presents with symptoms in one leg but with signs in both; the patient will complain of weakness, incoordination, or numbness and tingling in one lower limb and prove to have bilateral Babinski signs and other evidence of bilateral corticospinal and posterior column disease.

Passive flexion of the neck may induce a tingling, electric-like feeling down the shoulders and back and, less commonly, down the anterior thighs. This phenomenon is known as a *Lhermitte sign*, although it is more a symptom than a sign and was originally described by Babinski in a case of cervical cord trauma. Lhermitte's contribution was to draw attention to the frequent occurrence of this phenomenon in MS. It is the manifestation of increased sensitivity of demyelinated axons to the stretch or pressure on the spinal cord induced by neck flexion.

Dull, aching *pain* in the low back is a common complaint, but its relation to the lesions of MS is uncertain. Sharp, burning, poorly localized, or characteristic lancinating-radicular pain, localized to a limb or discrete part of the trunk, occurs but is infrequent. Nevertheless, these types of pain, presumably caused by demyelinating foci involving the root entry zones, have a few times been the presenting feature of the disease or have appeared at any time in established cases of the disease ([Ramirez-Lassepas et al](#)).

Other common modes of onset are optic neuritis, transverse myelitis, cerebellar ataxia, brainstem symptoms (vertigo, facial pain or numbness, dysarthria, diplopia), paresthesias in one limb, and disorders of micturition. These modes of presentation are often features of the established disease as well. They may pose diagnostic questions that at least have only conjectural answers, since they may represent disease other than MS. The more common presentations of MS are considered in the following paragraphs.

Optic Neuritis In about 25 percent of all MS patients (and in a larger proportion of children), the initial manifestation is an episode of *retrobulbar* or *optic neuritis*. Characteristically, over a period of several days, there is partial or total loss of vision in one eye. Some patients, for a day or two before the visual loss, experience pain within the orbit, worsened by eye movement or palpation of the globe. Rarely, the visual loss is steadily progressive for several weeks, mimicking a compressive lesion or intrinsic tumor of the optic nerve ([Ormerod and McDonald](#)). Usually a scotoma involving the macular area and blind spot (cecocentral) can be demonstrated, but a wide variety of other field defects may occur, rarely even hemianopic ones (sometimes homonymous). In some patients, both optic nerves are involved, either simultaneously or, more commonly, within a few days or weeks of one another, and at least 1 in 8 patients will have repeated attacks. Serial examinations may disclose evidence of swelling, or edema, of the optic nerve head (papillitis) in about half the patients. The occurrence of papillitis depends upon the proximity of the demyelinating lesion to the nerve head. Papillitis can be distinguished from the papilledema of increased intracranial pressure by the severe and acute visual loss that accompanies only the former. Subtle manifestations of optic nerve affection—such as atrophy of retinal nerve fibers or sheathing of retinal veins (page 261) and abnormalities of the visual evoked response (page 36)—should be sought in patients who have no visual complaints but are suspected of having MS. Only in cases of substantial visual loss is there a diminished pupillary response to light, but the pupil is said never to be dilated in ambient light. (Demyelination of the third nerve in its brainstem course, however, may be associated with a fixed enlargement of the pupil.) It will be recalled that the optic nerve is in fact a tract of the brain, and involvement of the optic nerves is therefore consistent with the rule that lesions of MS are confined to the CNS.

About one-third of patients with optic neuritis recover completely, and most of the remaining ones improve significantly, even those who present initially with profound visual loss and, later, pallor of the optic disc ([Slamovitis et al](#)). In a cohort of 397 patients enrolled in the Optic Neuritis Treatment Trial and examined 5 years after the initial attack of optic neuritis, visual acuity had returned to 20/25 or better in 87 percent of patients, and to 20/40 or better in 94 percent—even if there had been a recurrence of optic neuritis during the 5-year period. Moreover, the mode of treatment did not appear to influence the outcome. Dyschromatopsia, generally taking the form of a perceived desaturation of colors, is a frequent persistent finding. When improvement occurs, it begins usually within 2 weeks of onset, as is true of most acute manifestations of MS, perhaps sooner with corticosteroid treatment. Once improvement in neurologic function begins, it may continue for several months.

One-half or more of adult patients who present with optic neuritis alone will eventually develop other signs of MS. The prospective investigation of Rizzo and Lessell showed that MS developed in 74 percent of women and 34 percent of men by the 15th year after onset of visual loss. The risk is much lower if the initial attack of optic neuritis occurs in childhood (26 percent after 40 years of follow-up; Lucchinetti et al); this suggests that some instances of the childhood disease are of a different type. The longer the period of observation and the greater the care given to detection of mild cases, the greater the proportion of patients who are found to develop other signs of MS; however, most do so within 5 years of the original attack ([Ebers, Hely et al](#)). In fact, in many patients with clinically isolated optic neuritis, MRI has disclosed lesions of the cerebral white matter—suggesting that dissemination, albeit asymptomatic, had already occurred ([Jacobs et al](#), [Ormerod et al](#)). The Optic Neuritis Study Group has made the point, well known to neurologists, that the recurrence of optic neuritis greatly increases the chances of developing MS.

It is unclear whether optic neuritis that occurs alone and is not followed by other evidence of demyelinating disease is simply a restricted form of MS or a manifestation of some other disease process, such as postinfectious encephalomyelitis. By far the most common pathologic basis for optic neuritis is demyelinating disease, though it is known that a vascular lesion or compression of an optic nerve by a tumor or mucocele may cause a central or cecocentral scotoma.

Uveitis and sheathing of the retinal veins are other ophthalmic disorders that have a higher than expected incidence in patients with MS. The retinal vascular sheathing is due to T-cell infiltration, identical to that in typical plaques, but this is an anomalous finding, since the retina usually contains no myelinated fibers ([Lightman et al](#)).

The treatment of optic neuritis is discussed further on.

Acute Myelitis (Transverse Myelitis) This is the common designation for an acutely evolving inflammatory-demyelinating lesion of the spinal cord, which proves in most instances to be an expression of MS, of either monophasic or chronic (polyphasic) type. In this sense the myelitic lesion is analogous to that of optic neuritis. The term *transverse* in relation to the myelitis is somewhat imprecise, implying that all of the elements in the cord are involved in the transverse plane, usually over a short vertical extent. Instead, in MS, the spinal cord signs are asymmetrical and incomplete and involve only the long ascending and descending tracts.

Clinically, the illness is characterized by a rapidly evolving (several hours or days) symmetrical or asymmetrical paraparesis, a sensory level on the trunk, sphincteric dysfunction, and bilateral Babinski signs. The CSF shows a modest increase in lymphocytes and total protein but may be normal early in the illness. As many as one-third of patients report an infectious illness in the weeks preceding the onset of neurologic symptoms, in which case a monophasic postinfectious demyelinating disease is the likely cause of the myelitis. We have found that fewer than half the patients have evidence of an asymptomatic demyelinating lesion elsewhere in the nervous system or develop clinical evidence of dissemination within 5 years of the initial attack ([Ropper and Poskanzer](#)). Thus, acute transverse myelitis is somewhat less often an initial expression of MS than is optic neuritis. An alternative view is that the majority of cases of transverse myelitis will ultimately develop MS and that only lengthy follow-up will uncover the association. Other aspects of transverse myelitis are discussed in [Chap. 44](#), “Diseases of the Spinal Cord,” and under “Acute Disseminated Encephalomyelitis” later in this chapter.

A special problem is presented by patients with *recurrent myelitis* at one level of the spinal cord but in whom no other signs of demyelinating disease can be found by careful clinical examination or MR imaging. Some of them may even have oligoclonal bands in the CSF, which are commonly associated with MS (see further on). Enough cases of this limited nature have come to our attention to permit the conclusion that there is a recurrent form of spinal cord MS, in which cerebral dissemination is infrequent ([Tippett et al](#)). It should be mentioned that isolated recurrent myelitis occurs occasionally with lupus erythematosus, mixed connective tissue disease, or antiphospholipid antibody syndrome, or in the presence of other autoantibodies. An analogous situation pertains in respect to some instances of optic neuritis—repeated attacks that remain confined to the optic nerve.

Other Patterns of Multiple Sclerosis (See also “[variants of MS](#)”, page 965) Like the modes of onset cited above, other early manifestations of MS, in descending order of frequency, are unsteadiness in walking, brainstem symptoms (diplopia, vertigo, vomiting, etc.), paresthesias or numbness of an entire arm or leg, facial pain, and disorders of micturition. In our experience, vertigo of central type has been a frequent initial sign of MS. Discrete manifestations—such as hemiplegia, trigeminal neuralgia or other pain syndromes, facial paralysis, deafness, or seizures—occur in a small proportion of cases. Most often the disease presents with more than one of the aforementioned symptoms. Another syndrome of note, occurring mainly in elderly women, is a slowly progressive cervical myelopathy with weakness and ataxia. This is particularly difficult to differentiate from cervical spondylosis.

Not infrequently a prominent feature of the disease is *nystagmus and ataxia*, with or without weakness and spasticity of the limbs—a syndrome that reflects involvement of the cerebellar and corticospinal tracts. Ataxia of cerebellar type can be recognized by scanning speech, rhythmic instability of the head and trunk, intention tremor of the arms and legs, and incoordination of voluntary movements and gait, as described in [Chap. 5](#). The combination of nystagmus, scanning speech, and intention tremor is known as *Charcot's triad*; while this group of symptoms is often seen in the advanced stages of the disease, most neurologists would agree that it is not a common mode of presentation. The most severe forms of cerebellar ataxia, in which the slightest attempt to move the trunk or limbs precipitates a violent and uncontrollable ataxic tremor, are observed among patients with long-standing MS. The responsible lesion probably lies in the tegmentum of the midbrain and involves the dentatorubrothalamic tracts and adjacent structures. Cerebellar ataxia may be combined with sensory ataxia, owing to involvement of the posterior columns of the spinal cord or medial lemnisci of the brainstem. In most cases of this type the signs of spinal cord involvement ultimately predominate; in others, the cerebellar signs are more prominent.

Diplopia is another common presenting complaint. It is due most often to involvement of the medial longitudinal fasciculi, producing an internuclear *ophthalmoplegia* (see page 289). The latter is characterized by paresis of the medial rectus on attempted lateral gaze, with a coarse nystagmus in the abducting eye; in MS, this abnormality is usually bilateral (unlike small pontine infarcts, which cause a unilateral internuclear ophthalmoplegia). As a corollary, *the presence of bilateral*

internuclear ophthalmoplegia presenting in a young adult is virtually diagnostic of MS. Occasionally, internuclear ophthalmoplegia in one direction is combined with a horizontal gaze paresis in the other, although this “one-and-a-half syndrome” is more typical of brainstem stroke (see also page 289). Other palsies of gaze (due to interruption of supranuclear connections) or palsies of individual ocular muscles (due to involvement of the ocular motor nerves in their intramedullary course) also occur, but less frequently. Additional manifestations of brainstem involvement include myokymia or paralysis of facial muscles, deafness, tinnitus, unformed auditory hallucinations (because of involvement of cochlear connections), vertigo—as noted above, vomiting (vestibular connections), and rarely stupor and coma. The occurrence of *transient facial hypesthesia or anesthesia or of trigeminal neuralgia* in a young adult should always suggest the diagnosis of MS, with involvement of the intramedullary fibers of the fifth cranial nerve.

Symptoms and Signs in the Established Stage of the Disease When the diagnosis of MS has become virtually certain, a number of clinical syndromes are observed to occur with regularity. Approximately one-half of the patients will manifest a clinical picture of *mixed or generalized type* with signs pointing to involvement of the optic nerves, brainstem, cerebellum, and spinal cord. Another 30 to 40 percent will exhibit varying degrees of spastic ataxia and deep sensory changes in the extremities, i.e., essentially a *spinal form of the disease*. In either case, an asymmetrical spastic paraparesis is probably the most common manifestation of progressive MS. A predominantly *cerebellar or pontobulbarcerebellar form* will be noted in only about 5 percent of cases and an *amaurotic form* in a like number. Thus the mixed and spinal forms together have made up at least 80 percent of our clinical material.

Traditional teaching has overemphasized the frequency of *euphoria*, a pathologic cheerfulness or elation that seems inappropriate in the face of the obvious neurologic deficit. (Charcot spoke of this phenomenon as “stupid indifference” and Vulpian as “morbid optimism.”) Some patients do show this mental abnormality, always in association with other signs of cerebral impairment. In some instances it is manifestly a part of the syndrome of pseudobulbar palsy. A much larger number of patients, however, are *depressed*, irritable, and short-tempered as a reaction to the disabling features of the disease. Dalos and coworkers, in comparing MS patients with a group of traumatic paraplegics, found a significantly higher incidence of *emotional disturbance* in the former group, especially during periods of relapse. Other mental disturbances—such as a loss of retentive memory, a global *dementia*, or a confusional-psychotic state—also occur with some regularity in the advanced stages of the disease. The cognitive impairment is more in keeping with what has been ascribed to “subcortical dementia” (pages 450).

Symptoms of *bladder dysfunction*—including hesitancy, urgency, and incontinence—occur commonly with spinal cord involvement. Urinary retention, due to affection of sacral segments, is less frequent ([Fig. 26-5](#)). In males, these symptoms are often associated with impotence, a symptom that the patient may not report unless specifically questioned in this regard.

Abrupt attacks of neurologic deficit, lasting a few seconds or minutes and sometimes recurring many times daily, are a relatively infrequent but well-recognized feature of MS (see [Osterman and Westerbey](#)). Usually the attacks occur during the relapsing and remitting phase of the illness, rarely as an initial manifestation. These clinical phenomena are referable to any part of the CNS but tend to be stereotyped in an individual patient. The most common of these consist of dysarthria and ataxia, paroxysmal pain and dysesthesia in a limb, flashing lights, paroxysmal itching, or tonic seizures, taking the form of flexion (dystonic) spasm of the hand, wrist, and elbow with extension of the lower limb. The paroxysmal symptoms, particularly the tonic spasms, may be triggered by sensory stimuli or can be elicited by hyperventilation. The cause of paroxysmal phenomena is uncertain. They have been attributed by Halliday and McDonald to ephaptic transmission (“cross-talk”) between adjacent demyelinated axons within a lesion. Carbamazepine is usually effective in controlling the attacks.

These transitory symptoms appear suddenly, may recur frequently for several days or weeks, sometimes longer, and then remit completely, i.e., they exhibit the temporal profile of a relapse or an exacerbation. It is sometimes difficult to determine whether they represent an exacerbation or a new lesion. Years ago, Thygesen pointed out, in an analysis of 105 exacerbations in 60 patients, that there were new symptoms in only 19 percent; in the remainder there was only a recurrence of old symptoms. Another problem is that the original lesion may have been asymptomatic. For example, many of the patients found to have impaired visual evoked responses have never had symptomatic visual changes. Thus, new symptoms and signs may be manifestations of previously formed but asymptomatic plaques. However, the observations of Prineas and Connell indicate that symptoms and signs may progress without the appearance of new plaques. These and other factors need to be taken into consideration in evaluating the clinical course of the illness and the effects of a therapeutic program ([Poser](#)).

Unusually severe *fatigue* is another peculiar symptom of MS; it is often transient and more likely to occur when there is fever or other evidence of disease activity, but it can be a persistent complaint and a source of considerable distress. Depression may play a role in these recalcitrant cases.

A number of interesting manifestations of MS have come to our attention over the years and have given rise to difficulties in diagnosis. The occurrence of typical tic douloureux in young patients has already been mentioned; only their young age and the bilaterality of the pain in some of them raised the suspicion of MS, confirmed later by sensory loss in the face and other neurologic signs. Brachial, thoracic, or lumbosacral pain consisting mainly of thermal and algesic dysesthesias was a source of puzzlement in several other patients until additional lesions developed. Not infrequently the relatively acute occurrence of a right hemiplegia and aphasia first raised the probability of a cerebrovascular lesion; in still others, a more slowly evolving hemiplegia had led to the diagnosis of a cerebral glioma.

Approximately 3 percent of patients have focal seizures, usually in relation to an obvious cerebral lesion. Several times we have seen coma during relapse, and in each instance it continued to death. In one case it occurred in a 64-year-old woman who had had two previous episodes of nondisabling spinal MS at 30 and 44 years of age. A confusional psychosis with drowsiness was the initial syndrome in another patient whom we saw later with a relapse involving the cerebellum and spinal cord. Another unusual syndrome is one of slow intellectual decline with slight cerebellar ataxia. A 10-year, slowly progressive cerebellar ataxia in an adolescent girl was another perplexing variant until she later developed internuclear ophthalmoplegia. A rapid onset of ascending paralysis of legs, bladder and bowel, and trunk with severe pain in sacral parts, areflexia, and a mononuclear pleocytosis of 1600 cells per cubic millimeter occurred in another of our patients and lasted 2 years before she began to walk again; earlier she had had diplopia and retrobulbar neuritis.

Repeatedly, seemingly more in recent years, we have observed patients whose illness satisfied all the clinical criteria for the diagnosis of MS except for the onset of symptoms in the sixth or seventh decade. Presumably we were witnessing the late deteriorative phase of the illness, earlier symptoms having been forgotten or having never been recognized. As mentioned in the chapter on spinal cord disease, some instances of MS in late adult life take the form of a slowly progressive cervical myelopathy.

Variants of MS

Several variants of MS merit more extended discussion. They are acute MS, neuromyelitis optica, acquired Schilder disease, and the conjunction of MS and polyneuropathy.

Acute Multiple Sclerosis Rarely, MS takes a rapidly progressive and highly malignant form. A combination of cerebral, brainstem, and spinal manifestations evolves over a few weeks, rendering the patient stuporous, comatose, or decerebrate, with prominent cranial nerve and corticospinal abnormalities. Death may end the illness within a few weeks to months without any remission having occurred. At autopsy the lesions (unlike those of acute disseminated encephalomyelitis) are of macroscopic dimensions, typical of the acute plaques of MS. The only difference from the usual form of MS is that many plaques are of the same age and the confluence of many perivenous zones of demyelination is more obvious. Two of our most striking examples of this rapidly fatal form were in a 6-year-old girl and a 16-year-old boy, both of whom died within 5 weeks of the onset of symptoms. Another was a 30-year-old man who lived 2 months. In none of them had there been a preceding exanthem or inoculation or any symptoms suggestive of demyelinative disease. Usually the CSF shows a brisk cellular response.

Nonfatal clinical cases of similar type in children, adolescents, and young adults are admitted to our hospitals once or twice a year. Some have responded to high doses of intravenous corticosteroids; others worsened while receiving this medication. We have also had experience with two patients who improved rapidly after the institution of plasma exchange treatments, similar to the report by [Rodriguez and coworkers](#). However, it is clear that most patients with acute myelitis do not respond to this treatment. Some have made an astonishing recovery after several months, and a few have then remained well for 25 to 30 years. Others have relapsed, and the subsequent clinical course was typical of MS.

Most neurologists are familiar with similar epi-sodes of acute deterioration that punctuate otherwise typical cases of MS. These aggressive relapses occur most often in the first year of illness and in middle-aged patients and take the form of an exacerbation of a preexisting myelopathy in combination with a new brainstem syndrome. After a severe episode of this sort or multiple ones, a few of the lesions are cavitating rather than demyelinative.

It seems to the authors that more than one disease is being included in the clinical category of acute MS. One type conforms in its temporal profile to a rather protracted form of acute disseminated encephalomyelitis—an acute monophasic illness extending over 4 to 8 weeks akin to some of the Japanese post-rabies

inoculation cases ([Shiraki and Otani](#)). Others subsequently prove to be typical polyphasic MS. The main consideration in differential diagnosis is a CNS vasculitis.

Neuromyelitis Optica (Devic Disease, Necrotic Myelopathy; see also [Chap. 46](#)) The simultaneous or successive involvement of optic nerves and spinal cord has been convincingly documented. The combination was remarked upon by Clifford Albutt in 1870, and Gault (1894), stimulated by his teacher Devic, devoted his thesis to the subject. Devic endeavored to crystallize medical thought about a condition that has come to be known as neuromyelitis optica. Its principal features are the acute to subacute onset of blindness in one or both eyes, preceded or followed within days or weeks by a transverse or ascending myelitis ([Mandler et al](#)). The spinal cord lesions in cases of neuromyelitis optica are often necrotizing rather than purely demyelinative in type, leading eventually to cavitation; as would be expected, the clinical effects are more likely to be permanent than those of demyelination. A few of the patients have been children; in a number of instances, they suffered only a single episode of neurologic illness.

Although it is true that cases corresponding to this prototype are seen on occasion in every large medical center and at all age periods, the isolation of such an entity on clinical grounds alone has been unsatisfactory. Most of our patients have proved by subsequent clinical developments, and in a few instances by autopsy, to have chronic relapsing MS. In one notable example, where hemiplegia and aphasia were followed within 2 weeks by a necrotizing myelitis from which there was no recovery, the patient later developed typical attacks of MS, including retrobulbar neuritis. At autopsy, more than 15.0 cm of the spinal cord had been destroyed, reducing it to a collapsed membranous tube. Elsewhere the lesions were typically demyelinative.

One might conclude from cases such as these that neuromyelitis optica is but a variant form of MS (or some other type of demyelinative disease). Many cases of neuromyelitis optica, however, stand apart from MS by virtue of a number of distinctive clinical and pathologic features—namely, failure to develop brainstem, cerebellar, or cerebral demyelinative lesions and normality on MRI of the cerebral white matter, even after several years of illness; almost uniform absence of oligoclonal bands and other abnormalities of IgG in the spinal fluid; and finally the necrotizing and cavitary nature of the spinal cord lesion, affecting white and gray matter alike, with prominent thickening of vessels but without inflammatory infiltrates. On the basis of these differences, Mandler and O’Riordan and their colleagues and others have favored the separation of Devic disease from MS. For reasons mentioned above, we are uncertain that the distinction is quite so clear. Insofar as the cause neither of MS nor of Devic disease is known, uncertainties about the relationship of these diseases cannot be resolved with finality. Also, acute disseminated encephalomyelitis may occasionally present as neuromyelitis optica.

There also exists a progressive and saltatory *subacute necrotic myelopathy* without optic neuritis that shares all the myelopathic features of Devic disease and, in our view, probably represents the same entity ([Katz and Ropper](#)). The differential diagnosis is broader and includes arteriovenous malformation and infarction of the cord.

The treatment of neuromyelitis optica and of subacute necrotic myelopathy has been largely unsuccessful, most cases progressing despite aggressive therapy, including high-dose corticosteroids and cyclophosphamide.

Diffuse Cerebral Sclerosis of Schilder ([Schilder](#) Disease, Encephalitis Periaxialis Diffusa) Exceptionally the cerebrum is the site of massive demyelination, occurring in multiple foci or as a single large focus. Such cases are more frequent in childhood and adolescence than in adult life.

The term *diffuse sclerosis* was probably first used by Strumpell (1879) to describe the hard texture of the freshly removed brain of an alcoholic; later the term was applied to widespread cerebral gliosis of whatever cause. In 1912, Schilder described an instance of what he considered to be “diffuse sclerosis.” The case was that of a 14-year-old girl with progressive mental deterioration and signs of increased intracranial pressure, terminating fatally after 19 weeks. Postmortem examination disclosed large, well-demarcated areas of demyelination in the white matter of both cerebral hemispheres as well as a number of smaller demyelinative foci, resembling the common lesions of MS. Because of the similarities of the pathologic changes to those of MS (prominence of the inflammatory reaction and relative sparing of axis cylinders), Schilder called this disease *encephalitis periaxialis diffusa*, bringing it in line with *encephalitis periaxialis scleroticans*, a term that Marburg had used to describe a case of acute MS. Unfortunately, in subsequent publications, Schilder used the same term for two other conditions of different type. One appears to have been a familial leukodystrophy (adrenoleukodystrophy) in a boy, and the other, quite unlike either of the first two cases, was suggestive of an infiltrative lymphoma. The last two reports seriously confused the subject, and for many years the terms *Schilder’s disease* and *diffuse sclerosis* were indiscriminately attached to many different conditions.

One group of diseases of the cerebral white matter, which can be readily culled from the overall category of diffuse sclerosis, is the leukodystrophies, including adrenoleukodystrophy of boys and young men; globoid-cell leukodystrophy of Krabbe; sudanophilic leukodystrophy; and metachromatic leukodystrophy—all of which may involve peripheral nerves as well as the CNS tissue. The leukodystrophies (discussed in detail in [Chap. 37](#)) are characterized clinically by progressive visual failure, mental deterioration, and spastic paralysis and pathologically by massive and more or less symmetrical destruction of the white matter of the cerebral hemispheres. In each of them there is a specific inherited biochemical defect in the metabolism of myelin proteolipids.

If one sets aside the hereditary metabolic leukodystrophies and other childhood disorders of cerebral white matter that were incorrectly included under the rubric of “Schilder’s disease” or “diffuse sclerosis,” there remains a characteristic group of cases that does indeed correspond to Schilder’s original description. These cases are nonfamilial and are most frequently encountered in children or young adults. As with the case reported by [Ellison and Barron](#), the disease may follow the course of MS. Clinically these cases run a progressive course, either steady and unremitting or punctuated by a series of episodes of rapid worsening. In rare instances the disease may become arrested for many years, or the patient may even improve for a time. Dementia, homonymous hemianopia, cerebral blindness and deafness, varying degrees of hemiplegia and quadriplegia, and pseudobulbar palsy are the usual clinical findings. Optic neuritis may occur before or after the cerebral symptoms. The CSF may show changes similar to those in chronic relapsing MS, but often there are no oligoclonal bands; instead, myelin basic protein is found in large quantity in the CSF. Death occurs in most patients within a few months or years, but some survive for a decade or longer. In the differential diagnosis, a diffuse cerebral neoplasm, adrenoleukodystrophy, and progressive multifocal leukoencephalopathy ([Chap. 33](#)) are the main considerations.

The characteristic lesion in these cases is a large, sharply outlined, asymmetrical focus of myelin destruction often involving an entire lobe or cerebral hemisphere, typically with extension across the corpus callosum and affection of the opposite hemisphere ([Fig. 36-3](#)). In some cases both hemispheres may be symmetrically involved. A careful examination of the optic nerves, brainstem, and spinal cord often discloses the typical discrete lesions of MS. Histologically, the large single focus as well as the smaller disseminated ones show the characteristic features of MS.

Figure 36-3 Diffuse cerebral sclerosis ([Schilder](#) disease). MR image showing large asymmetrical foci of involvement of white matter in a 12-year-old boy, 2 1/2 months after onset of symptoms. The clinical picture was one of rapidly worsening episodes of bilateral hemiplegia and hemianopia. (From Bisese JH, *Cranial MRI*, New York, McGraw-Hill, 1991, by permission.)

Poser’s review of the literature in 1957 uncovered 105 cases that could be designated as the Schilder type of diffuse sclerosis in the original sense of the term. In 33 of these, the only lesions were the extensive areas of demyelination involving the centrum ovale; most of the patients in this group were children, and the disease had a tendency to take a subacute progressive course. In 72 patients, in addition to the large foci in the cerebral white matter, isolated demyelinative plaques were found in other parts of the CNS; the age of onset in this latter group was similar to that of chronic, relapsing MS; frequently, the illness ran a protracted and remitting course. These findings were elaborated by [Poser and colleagues](#) in a subsequent (1986) review of this subject. It is apparent that diffuse cerebral sclerosis of this type must

be closely related to MS and may indeed be a variant of it, as Schilder originally proposed.

The *concentric sclerosis of Balo* is probably a variety of Schilder disease, which it resembles in its clinical aspects and in the overall distribution of its lesions. The distinguishing feature is the occurrence of alternating bands of destruction and preservation of myelin in a series of concentric rings. The occurrence of lesions in this pattern suggests the centrifugal diffusion of some factor that is damaging to myelin. A similar pattern of lesions, although far less extensive, is seen in occasional cases of chronic relapsing MS.

Multiple Sclerosis in Conjunction with Peripheral Neuropathy From time to time there have been patients with MS who also have a polyneuropathy or mononeuropathy multiplex. This relationship always invites speculation and controversy. The rarity of the combination suggests a purely coincidental occurrence, perhaps with an underlying disease as an explanation (e.g., Lyme disease, AIDS). Another view, expressed by Thomas et al and by [Mendell et al](#), is that an autoimmune demyelination has been incited in both spinal cord and peripheral nerve, the latter taking the form of a chronic inflammatory polyradiculoneuropathy. Of course, radicular and neuropathic symptoms, motor and/or sensory, can result from the involvement of myelinated fibers in the root entry zone of the cord or fibers of exit in the ventral white matter. And in the late stages of MS there is always the possibility of vitamin deficiency polyneuropathy or multiple pressure palsies.

Laboratory Findings

Cerebrospinal Fluid In about one-third of all MS patients, particularly those with an acute onset or exacerbation, there may be a slight to moderate mononuclear pleocytosis (usually less than 50 cells per cubic millimeter). In rapidly progressive cases of neuromyelitis optica (see above) and in certain instances of severe demyelinating disease of the brainstem, the total cell count may reach or exceed 100 and rarely 1000 cells per cubic millimeter; the greater proportion of these in the hyperacute cases may be polymorphonuclear leukocytes. This pleocytosis may in fact be the only measure of activity of the disease. Other laboratory tests (except perhaps for myelin basic protein, see below) do not reflect the activity of the disease.

Also, in about 40 percent of patients, the total protein content of the CSF is increased. The increase is slight, however, and a concentration of more than 100 mg/dL is so unusual that the possibility of another diagnosis should be entertained. More importantly, the proportion of gamma globulin (essentially IgG) is increased (greater than 12 percent of the total protein) in about two-thirds of patients. Another less frequently used diagnostic measure is the IgG index, which is obtained by measuring albumin and gamma globulin in both the serum and CSF and using the following formula:

$$\frac{\text{CSF IgG/serum IgG}}{\text{CSF alb/serum alb}}$$

A ratio of more than 1.7 indicates the probability of MS.

It has been shown that the gamma globulins in the CSF of patients with MS are synthesized in the CNS ([Tourtellotte and Booe](#)) and that they migrate in agarose electrophoresis as abnormal discrete populations, so-called *oligoclonal bands*. A simple method for demonstrating these bands uses readily available commercial reagents and apparatus. Determination of the IgG index and testing for oligoclonal IgG bands is done in most commercial and hospital laboratories and will show CSF abnormalities in more than 90 percent of cases of MS. Such bands also appear in the CSF of patients with syphilis and subacute sclerosing panencephalitis—disorders that should not be difficult to distinguish from MS on clinical grounds. The demonstration of oligoclonal bands in the CSF and not in the blood is particularly helpful in confirming the diagnosis of MS, but these are not always found with the first attack or even in the later stages of the disease. The presence of such bands in a first attack of MS is predictive of chronic relapsing MS, according to Moulin and coworkers and others.

It has also been shown, by the use of a sensitive radioimmunoassay, that the CSF of many patients contains high concentrations of myelin basic protein (MBP) during acute exacerbations of MS and that these levels are lower or normal in slowly progressive MS and normal during remissions of the disease ([Cohen et al](#)). Other lesions that destroy myelin (e.g., infarction) can also increase the level of MBP in the spinal fluid. Thus the assay is not particularly useful as a diagnostic test. The method is not simple but is available commercially.

When cells, total protein, gamma globulin, and oligoclonal bands are all taken into account, some abnormality of the spinal fluid will be found in the great majority of patients with MS. At present the measurement of gamma globulins as a fraction of total protein and oligoclonal bands in the CSF are the most reliable of the chemical tests for MS. We are not convinced that other, more complicated laboratory procedures, such as CSF measurements of globulin production or MBP, provide additional diagnostic sensitivity.

MRI in MS It is now widely appreciated that MRI is the most helpful ancillary examination in the diagnosis of MS, by virtue of its ability to reveal asymptomatic plaques in the cerebrum, brainstem, optic nerves, and spinal cord (see [Fig. 36-1](#) and [Fig. 36-2](#)). Our experience accords with that of Stewart and coworkers, who found multifocal lesions in 80 percent of their established cases. In a series of 114 patients with clinically definite MS, Ormerod and colleagues recorded T2-intense periventricular MRI abnormalities in all but 2 patients and discrete cerebral white matter lesions in all but 12. It is remarkable that even when there are a multitude of cerebral lesions, they tend to be asymptomatic; the opposite is generally the case with spinal cord lesions.

It should be stressed that foci of periventricular hyperintensity are observed with a variety of pathologic processes and even in normal persons, particularly older ones; in the latter cases, the periventricular changes are usually milder in degree and smoother in outline than the lesions of MS. The signal characteristics of MS lesions vary somewhat depending on the field strength of the magnet and the ratio of T1 and T2 weighting—but, curiously, not on the age of the lesions. In general, MS plaques that are hypointense (white) on T2-weighted images may be even more strikingly obvious on FLAIR images. Lesions that have undergone some degree of cavitation, as happens only occasionally, are hypointense on T1-weighted images. The discrete cerebral lesions of MS do not always impart a specific MR imaging appearance; but the finding, on T2-weighted images, of several asymmetrical, well-demarcated lesions immediately adjacent to the ventricular surface usually denotes MS. These areas typically extend into the centrum semiovale and may reach the convolutional white matter. In advanced cases the lesions become confluent, usually at the poles of the ventricles. *Especially diagnostic are oval or linear regions of demyelination, oriented perpendicularly to the ventricular surface and corresponding to the radially oriented fiber bundles of the white matter and periventricular veins.* When viewed in sagittal images, they extend outward from the corpus callosum and have been called “Dawson fingers.” Some lesions display contrast enhancement when acute; these can be brought out by administration of double or triple the usual dose of gadolinium. The spectrum of these changes has been commented upon by [Berry and colleagues](#). Infrequently, a large acute lesion may have a mass effect and a ring-like contrast-enhancing border, resembling a glioblastoma or an infarct, and the correct diagnosis may be made only by biopsy. A series of focal tumor-like lesions of the brain, the demyelinating nature of which only became evident after biopsy, has been reported by [Kepes](#). Serially performed MRI can demonstrate the progress of the disease. As with other laboratory procedures, MRI changes assume diagnostic significance only if they are consistent with the clinical findings.

Evoked Potentials and Other Tests When the clinical data point to only one lesion in the CNS, as often happens in the early stages of the disease or in the spinal form, a number of other sensitive physiologic and radiologic tests may establish the existence of additional asymptomatic lesions. These tests include visual, auditory, and somatosensory evoked responses and the less easily available perceptual delay on visual stimulation; electro-oculography; altered blink reflexes; and a change in flicker fusion of visual images. Halliday and McDonald reported abnormalities in one or more of these tests in 50 to 90 percent of a series of MS patients. At our hospitals, abnormal visual evoked responses have been found in 70 percent of patients with the clinical features of definite MS and 60 percent of patients with probable or possible MS. The corresponding figures for somatosensory evoked responses were 69 percent and 51 percent, and for brainstem auditory evoked responses (usually prolonged interwave latency or decreased amplitude of wave 5), 47 percent and 20 percent, respectively (see [Chap. 2](#)).

CT scanning may also demonstrate cerebral lesions, often unexpectedly. Doubling the dose of contrast material and delaying the scan for an hour postinfusion increases the yield of lesions during exacerbations of MS. Two points worth noting about the CT scan are that acute plaques can appear as contrast-enhanced ring lesions, simulating abscess or tumor, and that some contrast-enhanced periventricular lesions become radiologically inevident after steroid treatment, as occurs also with CNS lymphoma.

As mentioned earlier, the ancillary examinations in common use—MRI, evoked potentials, and oligoclonal bands in the CSF—have broadened the criteria for the diagnosis of MS. Often these procedures disclose the presence of multiple plaques when clinical examination has failed to do so. Stated differently, the time-honored rule that the diagnosis of MS requires evidence of “lesions scattered in time and space” is still valid, but the evidence now includes certain laboratory findings as well as purely clinical ones. Finally, it should be noted that no single laboratory procedure—including MRI, altered blood-brain barrier, immunoglobulin synthesis, and MBP in CSF—when viewed alone or at a single time is a totally reliable marker for MS.

Clinical Course and Prognosis

The intermittency of the clinical manifestations—the disease advancing in a series of attacks, each permitting less and less remission—is perhaps the most important clinical attribute of MS. Some patients will have a complete clinical remission after the initial attack, or, rarely, there may be a series of exacerbations, each with complete remission; such exacerbations may be severe enough to have caused quadriplegia and pseudobulbar palsy. The relapse rate is 0.3 to 0.4 attacks per year according to the calculations of McAlpine and Compston, but the interval between the opening symptom and the first relapse is highly variable. It occurred within 1 year in 30 percent of McAlpine's cases and within 2 years in another 20 percent. A further 20 percent relapsed in 5 to 9 years, and another 10 percent in 10 to 30 years. Not only the length of this latent interval is remarkable, but also the fact that the pathologic process can remain potentially active for such a long time.

Weinshenker and colleagues, on the basis of observations in 1099 MS patients over a 12-year period, have identified a number of features of the early clinical course that are predictive, in a general way, of the outcome of the illness. Perhaps not surprisingly, they found that a high degree of disability, as measured by the [Kurtzke Disability Status Scale](#) (DSS 6, indicating assistance required for walking), was reached earlier in patients with a higher number of attacks, a shorter first interattack interval, and a shorter time to reach a state of moderate disability (DSS 3). Kurtzke had earlier reported that the feature most predictive of long-term disability was the degree of disability at 5 years from the first symptom.

After a number of years there is an increasing tendency for the patient to enter a phase of slow, steady, or fluctuating deterioration of neurologic function, attributable to the cumulative effect of increasing numbers of lesions. However, in about 10 percent of cases the clinical course is almost evenly progressive from the beginning (primary progressive multiple sclerosis; see [Thompson et al](#)). In these latter cases the disease usually takes the form of a chronic asymmetrical spastic paraparesis and probably represents the most frequent type of obscure myelopathy observed by the authors. In Thompson's review of such cases, there was an absence of progression of the MRI findings, a negligible response to therapy, and a poor outcome.

Few if any factors are known to affect the course of the disease. Contrary to commonly held opinion, pregnancy does not have an adverse effect on MS. In fact, pregnancy is typically associated with clinical stability or even with improvement, as it is in a number of autoimmune diseases. The average relapse rate in established cases declines in each trimester, reaching a level less than one-third of the expected rate by the third trimester. However, there appears to be an increased risk of exacerbations, up to twofold, in the first few months postpartum ([Birk and Rudick](#)). An extensive study of 269 pregnancies by [Confavreux and colleagues](#) established a rate of relapse of 0.7 per woman per year before pregnancy and rates of 0.5 in the first, 0.6 in the second, and 0.2 in the third trimester, the rate then increasing substantially to 1.2 in the first three postpartum months.

The duration of the disease is exceedingly variable. A small number of patients die within several months or years of the onset, but the average duration is in excess of 30 years. A 60-year appraisal of the resident population of Rochester, Minnesota, disclosed that 74 percent of patients with MS survived 25 years, as compared with 86 percent of the general population. At the end of 25 years, one-third of the surviving patients were still working and two-thirds were still ambulatory ([Percy et al](#)). Other statistical analyses have given a far less optimistic prognosis; these have been reviewed by [Matthews](#). Patients with mild and quiescent forms of the disease are, of course, less likely to be included in such surveys.

Differential Diagnosis

In the usual forms of MS—that is, in those with a relapsing and remitting course and evidence of disseminated lesions in the CNS—the diagnosis is rarely in doubt. Only meningovascular syphilis, certain rare forms of cerebral arteritis, vascular malformations (cavernous angiomas) of the brainstem or spinal cord with multiple episodes of bleeding, lupus erythematosus, and Behçet disease could possibly simulate relapsing MS, and each of these has its own characteristic diagnostic features. The list can be stretched by inclusion of corticosteroid-responsive cerebral lymphoma, intravascular lymphoma, and the numerous causes of multiple, well-demarcated white matter abnormalities on MRI, such as embolic infarcts, progressive multifocal leukoencephalopathy, Lyme disease, tumors, etc. Difficulties are most likely to arise when the standard clinical criteria for the diagnosis of MS are lacking, as occurs in the acute initial attack of the disease and in cases with an insidious onset and slow, steady progression. Other *features that call for caution in diagnosis of MS are an absence of symptoms and signs of optic neuritis, the presence of amyotrophy, entirely normal eye movements, a hemianopic field defect, pain as the predominant symptom, and a progressive nonremitting illness that begins in youth*.

As has been stated, *the initial attack of MS* may mimic acute labyrinthine vertigo or tic douloureux (trigeminal neuralgia). Careful neurologic examination of such patients usually discloses other signs of a brainstem lesion; the CSF examination may be particularly helpful in these circumstances. Extensive brainstem demyelination of subacute evolution, involving tracts and cranial nerves sequentially, may be mistaken for a pontine glioma. With brainstem symptoms of acute onset, there may be difficulty in distinguishing an MS plaque from a small infarction due to a basilar branch occlusion. In several patients that we have observed, recurrent bleeding from multiple cavernous vascular malformations and small brainstem arteriovenous malformations simulated MS. With MRI, visualization of blood products surrounding the small vascular lesions clarifies the diagnosis (see [Fig. 34-26](#)). Sequential MRI and the course of the illness settle the matter; symptoms of brainstem MS remit as a rule, and to a surprisingly complete degree in many cases.

Disseminated encephalomyelitis (see further on) is an acute illness with widely scattered small demyelinative lesions, but it is self-limited and monophasic; furthermore, fever, stupor, and coma, which are characteristic, rarely occur in MS.

In systemic lupus erythematosus and rarely in other autoimmune diseases (mixed connective tissue disease, Sjögren syndrome, scleroderma, primary biliary cirrhosis), there may be multiple lesions of the CNS white matter. These may parallel the activity of the underlying immune disease or the level of autoantibodies, such as those against native DNA or phospholipids, but myelitis or lesions in the cerebral hemispheres are known to occur before other organ systems are affected. Conversely, between 5 and 10 percent of MS patients have antinuclear or anti-double-stranded DNA antibodies without signs of lupus. In addition, it has been pointed out that the relatives of patients with MS have a higher than expected incidence of autoantibodies of various types, suggesting an as yet unproved connection between autoimmune disease and MS. On MRI, the lesions of lupus appear similar to plaques, and both the optic nerve and the spinal cord may be involved, even repeatedly, in a succession of attacks resembling MS. Nevertheless, in our pathologic material, the lesions represent small zones of infarct necrosis rather than demyelination and are traceable to small-vessel vasculitis or cardiogenic embolism. In a few instances, inflammatory demyelination without vascular changes may be seen. It is best for the moment to consider these as special manifestations of lupus or related diseases that mimic MS.

Periarteritis nodosa or vasculitis confined to the nervous system may produce multifocal lesions simulating MS. The distinction may be particularly difficult in rare instances of the vasculitic process in which the neurologic manifestations take the form of a relapsing or steroid-responsive myelitis. In these cases, the CSF may contain 100 or more white blood cells per cubic millimeter and there may be no evidence of disease elsewhere in the nervous system. Occasionally, a young individual with Lyme disease may have complaints of inordinate fatigue and vague neurologic symptoms coupled with T-2 bright lesions on the cranial MRI. Close attention to the characteristic history (rash, arthritis, etc.) and serologic findings should permit the distinction of the two diseases.

The distinguishing features of Behçet disease are recurrent iridocyclitis and meningitis, mucous membrane ulcers of mouth and genitalia, and symptoms of articular, renal, lung, and multifocal cerebral disease. The chronic forms of brucellosis in the Mediterranean regions and Lyme borreliosis throughout North America and Europe may cause myelopathy or encephalopathy with multiple white matter lesions on imaging studies, but in each case the history and other features of the disease help to identify the infectious illness (see [Chap. 32](#)).

The *purely spinal form of MS*, presenting as a progressive spastic paraparesis, hemiparesis, or—in several of our cases—spastic monoparesis of a leg with varying degrees of posterior column involvement, is a special source of diagnostic difficulty. A tendency to affect older women has already been mentioned. Such patients require careful evaluation for the presence of spinal cord compression due to neoplasm or cervical spondylosis. Radicular pain at some point in the illness is a frequent manifestation of these disorders and is much less frequent in MS. Pain in the neck, restricted mobility of the cervical spine, and severe muscle wasting due to spinal root involvement, as is sometimes seen in spondylosis, are almost unknown in MS. Moderate atrophy of the first dorsal interosseus muscles has, however, been commented on as a common finding in MS. As a general rule, loss of abdominal reflexes, impotence in males, and disturbances of bladder function occur early in the course of demyelinative myelopathy but late or not at all in cervical spondylosis. The CSF protein in the latter condition is apt to be significantly elevated, but the other typical protein abnormalities of MS are absent. The definitive tests are MRI and CT myelography and perhaps electromyography (EMG), which is sensitive to the radicular features of spondylosis. Every patient with progressive spastic paraparesis in whom the neurologic signs are limited to the spinal cord should be investigated by these methods. A special problem arises when imaging procedures reveal a regional swelling of the spinal cord, which happens occasionally with an episode of myelitis and suggests a tumor. In several of our patients this finding has led to fruitless laminectomy.

The problem of differentiating MS from tropical spastic paraparesis (human lymphotropic virus, myelitis of the HTLV 1 type) and progressive familial spastic paraplegia may also arise occasionally. Amyotrophic lateral sclerosis (ALS) and subacute combined degeneration (SCD) of the cord should not be confused with MS. Amyotrophic lateral sclerosis can be identified by the presence of muscle wasting, fasciculations, and the absence of sensory involvement, while SCD is characterized by symmetrical involvement of the posterior and then lateral columns of the spinal cord, low serum levels of vitamin B₁₂, gastric achlorhydria, the presence of multilobed polymorphonuclear cells, megaloblastic marrow and macrocytic anemia in many cases, high serum concentrations of methylmalonic acid and homocystine, and defective absorption of vitamin B₁₂ as determined by the Schilling test (page 1122).

Platybasia and basilar impression of the skull should also be considered in the differential diagnosis, but patients with these conditions have a characteristic shortening of the neck; careful radiographs of the base of the skull will be diagnostic. Neurologic syndromes resulting from the Chiari malformation, syringomyelia, and tumors of the foramen magnum, cerebellopontine angle, clivus, and other parts of the posterior fossa have been misdiagnosed as MS. In each of these instances, a solitary, strategically placed lesion may give rise to a variety of neurologic symptoms and signs referable to the lower brainstem and cranial nerves, cerebellum, and upper cervical cord and may give the impression of dissemination of lesions. It is an excellent clinical rule that a diagnosis of MS should not be made when all the patient's symptoms and signs can be explained by a single lesion in one region of the neuraxis.

Occasionally MS may be confused with the hereditary ataxias, particularly the spinocerebellar types. The latter are generally distinguished by their familial incidence and other associated genetic traits; by their insidious onset and slow, steady progression; and by their symmetry and stereotyped clinical pattern. Intactness of abdominal reflexes and sphincter function and the presence of pes cavus, kyphoscoliosis, and cardiac disease are other features that favor the diagnosis of a hereditary degenerative disorder (see [Chap. 39](#)). Finally, as mentioned above, the periventricular lesions of cerebral lymphoma—an increasingly common tumor—and angiocentric lymphoma (page 700) may closely resemble MS plaques on MRI and may also produce a multifocal, relapsing, steroid-responsive illness of the CNS. This last disease has been associated at times with oligoclonal bands in the spinal fluid.

Careful clinical appraisal will usually lead to accurate diagnosis, but the label of MS should not be attached to a patient until the evidence is unequivocal. Once such a label is applied, it tends to stick, and since the diagnosis of MS will explain almost any subsequent neurologic event, attention may be directed away from consideration of another, perhaps treatable disease.

Treatment

As one might expect, numerous forms of treatment have been proposed over the years, and many were thought to be successful, no doubt because of the remitting nature of the disease. To enumerate them all here would serve no useful purpose. The many therapeutic trials of recent years, utilizing mainly anti-inflammatory and immunosuppressive drugs, have been critically reviewed by [Matthews](#) and by [Ebers](#) and more recently by [Rudick and colleagues](#). On the basis of controlled clinical trials, only adrenocorticotrophic hormone (ACTH), methylprednisolone, prednisone, cyclophosphamide, and beta- interferon have proved to have a beneficial effect on the disease and on MRI lesions. Under the influence of the anti-inflammatory agents, recovery from an attack, including an attack of optic neuritis, appears to be hastened. However, a substantial group of patients with acute exacerbations fail to respond; in others, benefit is not apparent for a month or longer after the course of treatment has been completed. Also, there is no evidence that steroids have a significant effect upon the ultimate course of this disease or that they prevent recurrences, so there is little justification for steroid treatment over a period of many months or years.

Corticosteroids As to the dosage of corticosteroids for an acute attack, it has seemed to us important that a high dose be used initially to be effective, but this has been disputed, as noted below. The intravenous administration of massive doses of methylprednisolone (a bolus of 500 to 1000 mg daily for 3 to 5 days), followed by high oral doses of prednisone (beginning with 60 to 80 mg daily and tapering this dosage over a 12-day period) is generally effective in aborting or shortening an acute or subacute exacerbation of MS or of optic neuritis and is probably as effective as but far less cumbersome than the administration of ACTH, which was popular during the 1970s and 1980s. When it is impractical to administer parenteral methylprednisolone, one may substitute oral methylprednisolone—48 mg in a single daily dose for 1 week, followed by 24 mg daily for 1 week, and finally 12 mg daily for 1 week ([Barnes et al](#)). This has the advantage of avoiding hospitalization, but we have the impression that severe attacks, especially of myelitis, respond more quickly to high-dose intravenous medication. However, a randomized trial of oral and intravenous methylprednisolone in acute relapses of MS demonstrated no clear advantage of the intravenous regimen ([Barnes et al](#)).

We attempt to limit the period of corticosteroid administration to less than 2 weeks but prolong the period of tapering the drug if neurologic signs return. This brief period of corticosteroid administration generally produces few adverse effects, but some patients complain of insomnia and a few will develop depressive or manic symptoms. Patients who, because of clinical relapse upon withdrawal of the medication, require treatment for more than several weeks are subject to the effects of hypercortisolism, including the facial and truncal cosmetic changes of Cushing syndrome, hypertension, hyperglycemia and erratic diabetic control, osteoporosis, aseptic necrosis of the acetabulum, and cataracts; less often, there may be gastrointestinal hemorrhage and activation of tuberculosis. Modest potassium replacement is advisable. Alternate-day steroid treatment offers little benefit, in our experience. However, pulses of high-dose intravenous steroids, administered once each month, seem to keep some patients from having relapses and are better tolerated than the continuous administration of oral medication. It must be acknowledged that the corticosteroid regimens and dosages in common use are derived from anecdotal experience (the Optic Neuritis Treatment Trial being an exception) and that certain patients appear, at least for a period of time, to respond better to one or another method of treatment.

Treatment of Optic Neuritis The Optic Neuritis Treatment Trial, reported by [Beck and colleagues](#), cautioned against the use of oral prednisone in the treatment of acute optic neuritis (see also [Lessell](#)). In this randomized, controlled study involving 457 patients with acute optic neuritis, it was found that the use of intravenous methylprednisolone followed by oral prednisone did indeed speed the recovery from visual loss, although at 6 months there was little difference between patients treated in this way and those treated with placebo. However, treatment with oral prednisone alone increased the risk of new episodes of optic neuritis. In a subsequent randomized trial conducted by [Sellebjerg and colleagues](#), it was found that methylprednisolone 500 mg orally for 5 days had a beneficial effect on visual function at 1 and 3 weeks. However, at 8 weeks no effect could be shown (compared with the placebo-treated group), nor was there an effect on the subsequent relapse rate.

Interferon Beta and Copolymer I These are more recently introduced forms of treatment for patients with relapsing-remitting multiple sclerosis and give promise of modestly altering the natural history of the disease. Interferon beta-1b (Betaseron), a nonglycosylated bacterial cell product with an amino acid sequence identical to that of natural interferon beta, was the first of these agents to be tested (see [Arnason](#)). Several trials have now shown that the subcutaneous injection of this agent, every second day for up to 5 years, decreases the frequency and severity of relapses by almost one-third and also the number of new or enlarging lesions ("lesion burden") in serial MR images. A more recent large-scale trial (European Study Group) has extended the observations with interferon beta-1b to patients with the secondarily progressive type of MS; progression of the disease was delayed for 9 to 12 months in a study period of 2 to 3 years.

The treatment of relapsing-remitting MS with interferon beta-1a (a glycosylated mammalian-cell product, Avonex) is equally effective; it may be taken once weekly as an intramuscular injection (PRISMS Study Group). The dose currently used is 30 µg, or 6.6 million units. Copolymer I (glatiramer acetate), which was synthesized to mimic the actions of MBP, a putative autoantigen in multiple sclerosis, is given daily in subcutaneous doses of 20 mg. Glatiramer acetate (Copaxone) may be particularly useful in patients who become resistant, i.e. develop serum antibodies to interferon beta ([Rudick et al](#)).

Overall, the side effects of these agents have been modest, consisting mainly of flu-like symptoms, sweating, and malaise that begin several hours after the injection and persist for up to 14 h; they tend to abate with continued use of the agents, but some patients cannot tolerate them. The salutary effects of treatment are definite though not overwhelming, and difficulties in judging the clinical trials remain; these have been summarized by [Hughes and Sharrack](#). Treatment is somewhat tedious and quite expensive. The long-term effects remain to be clarified, particularly the significance of neutralizing antibodies and the reduction in MRI changes, and the extent to which the latter translate into clinical benefit.

Immunosuppressive Drugs A number of experimental agents that modify immune reactivity have been tried, with limited success. Drugs such as azathioprine and cyclophosphamide, as well as total lymphoid irradiation, have been given to small groups of patients and seem to have improved the clinical course of some ([Aimard et al](#), [Hauser et al](#), [Cook et al](#)). However, the risks of prolonged use of immunosuppressive drugs, including a risk of neoplastic change, will probably preclude their widespread use. Moreover, the careful study by the British and Dutch Multiple Sclerosis Azathioprine Trial Group attributed no significant advantage to treatment with this drug. For the chronic, progressive phase of the disease, an MS study group has reported a modest delay in the advance of the disease after a 2-year trial of prednisolone and cyclophosphamide. They caution, however, that the "burdensome and potentially serious toxicity must temper one's consideration of its use in this disease." At least one subsequent blinded, placebo-controlled study with cyclophosphamide has failed to show any benefit. In one trial involving patients with chronic progressive MS, weekly, low-dose oral methotrexate has made a slight clinical difference and produced some reduction in the volume of cerebral lesions on the MRI

compared with control cases ([Goodkin et al](#)). Because this regimen is well tolerated, it may still have some use in otherwise untreatable progressive cases.

Other Therapies There are no valid studies to substantiate claims that have been made for the value of synthetic polypeptides, hyperbaric oxygen, low-fat and gluten-free diets, or linoleate supplementation of the diet. As mentioned under “Acute Multiple Sclerosis,” there may be a role for plasma exchange ([Rodriguez et al](#)) and perhaps immunoglobulin in fulminant cases, but these have not been tested rigorously. One trial has shown some benefit, in patients with relapsing-remitting disease, of monthly infusions of intravenous immunoglobulin (0.2 g/kg) for 2 years ([Fazekas et al](#)).

General Measures These include the provision of an adequate period of bed rest and convalescence to ensure maximum recovery from the initial attack or exacerbation, prevention of excessive fatigue and infection, the use of all possible rehabilitative measures to postpone the bedridden stage of the disease (braces, chairs, ramps, lifts, cars with manual controls, etc.), and meticulous attention to the prevention of bedsores in the bedridden patient by the use of alternating-pressure mattresses, silicone gel pads, and other special devices.

Fatigue, a common complaint of MS patients, particularly in relation to acute attacks, responds to some extent to amantadine (100 mg morning and noon), modafinil (200 to 400 mg/day), or pemoline (20 to 75 mg each morning).

Disorders of bladder function may raise serious problems in management. Where the major disorder is one of urinary retention, bethanechol chloride may be helpful. In this situation, monitoring and reducing the residual urinary volume is an important means of preventing infection; volumes up to 100 mL are generally well tolerated. Some patients with severe bladder dysfunction, particularly those with urinary retention, benefit from intermittent catheterization, which they can learn to do themselves and which lessens the constant risk of infection from an indwelling catheter. More often the problem is one of urinary urgency and frequency (spastic bladder), in which case the use of propantheline (Pro-Banthine) or oxybutynin (Ditropan) may serve to relax the detrusor muscle ([Chap. 26](#)). These drugs are best used intermittently. Severe constipation is best managed with properly spaced enemas. Often a program of bowel training can be successfully undertaken.

In patients with severe spastic paralysis and painful flexor spasms of the legs, intrathecal infusion of baclofen through an indwelling catheter and implanted pump, as in other spastic states, is sometimes of value. The selective injection of botulinum toxin into the most hypertonic muscles may help some patients. Some patients with lesser degrees of spasticity have benefited from the oral administration of baclofen. Failing this measure, one of several surgical procedures—dorsal rhizotomy, myelotomy, crushing of the obturator nerves, and, most useful of all in severe cases, intrathecal baclofen infusion by pump—may give relief for a prolonged period.

The very severe and disabling tremor that is brought out by the slightest movement of the limbs, if unilateral, can be managed surgically by ventrolateral thalamotomy. Most surgical series report that about two-thirds of patients achieve a satisfactory reduction in their intention tremor ([Critchley and Richardson](#); [Geny et al](#)). In the experience of others, the results have not been quite this reliable. In the series of Hooper and Whittle, only three of ten MS patients who underwent thalamotomy for a severe tremor had sustained improvement. Hallett and colleagues have reported that severe postural tremor of this type can be improved by the administration of isoniazid (300 mg daily, increased by weekly increments of 300 mg to a dose of 1200 mg daily) in combination with 100 mg pyridoxine daily. How isoniazid produces its beneficial effects is not known. Variable success may also be achieved with carbamazepine or clonazepam.

The importance of an understanding and sympathetic physician in the care of patients with a chronic incapacitating neurologic disease of this kind cannot be overemphasized. Enlisting the support of physical and occupational therapists, visiting nurses, and social workers can be equally important. From the beginning, when the patients first inquire about the nature of their illness, they require advice about their daily routine, marriage, pregnancy, the use of drugs, inoculations, and so on. As indicated earlier, the term *multiple sclerosis* should not be introduced until the diagnosis is certain, and then it should be qualified by a balanced explanation of the symptoms, stressing always the optimistic aspects of the disease. Most patients desire an honest appraisal of their condition and prognosis; some consider the uncertainty of their prognosis worse than their actual disability.

ACUTE DISSEMINATED ENCEPHALOMYELITIS (ADEM)

Postinfectious, Postexanthem, Postvaccinal Encephalomyelitis

Some of these terms, used originally to refer to the neurologic sequelae of infectious fevers, were introduced into medicine in the late nineteenth century, but it was not until the late 1920s that Perdrau, Pette, Greenfield, and others identified a type of pathologic reaction common to a number of exanthems and vaccines. The current view of this entity is that it represents an acute demyelinative disease, distinguished pathologically by numerous foci of demyelination scattered throughout the brain and spinal cord; some are restricted to the cerebellum or spinal cord. These foci vary from 0.1 to several millimeters (when confluent) in diameter and invariably surround small and medium-sized veins. The axons and nerve cells are more or less intact. Equally distinctive is the perivenular inflammatory reaction; the perivascular spaces are infiltrated with lymphocytes and mononuclear cells and the adjacent regions of white matter are invaded by pleomorphic microglia corresponding to the zones of demyelination. Multifocal meningeal infiltration is another invariable feature but is rarely severe in degree.

An acute encephalitic, myelitic, or encephalomyelitic process of this type is observed in a number of clinical settings. In the originally described form, it occurred within a few days of onset of the exanthem of measles, rubella, smallpox, and chickenpox. Prior to widespread immunization against measles, an epidemic in a large city might have resulted in 100,000 cases of measles and clinically evident neurologic complications in 1 in 800 to 1 in 2000 cases. The mortality among patients with such complications ranged from 10 to 20 percent; about an equal number were left with persistent neurologic damage. The neurologic complications of measles alone provide sufficient justification for immunization against the disease. The incidence of encephalomyelitis was less following chickenpox and rubella and much less following mumps (the latter never seen in our material). In the past, a similar illness was observed to follow vaccination against rabies and smallpox and, reportedly, after administration of tetanus antitoxin (rare), as discussed further on. Now, however, most cases, clinically and pathologically indistinguishable from these two categories of acute disseminated encephalomyelitis, appear to develop after seemingly banal respiratory infections and after documented infections with Epstein-Barr, cytomegalovirus, and *Mycoplasma pneumoniae*; occasionally there is no clearly defined preceding illness or inoculation. Many instances of predominantly unifocal and nonrelapsing acute transverse myelitis may represent the same postinfectious process. The neurologic illness may coincide with the respiratory manifestations of the infection, in which case the term *parainfectious* may be appropriate. Rarely, it occurs after influenza and mumps (to be distinguished from the more common mumps meningitis).

Irrespective of the clinical setting in which it occurs, disseminated encephalomyelitis in its severe form is of grave import, because of the significant rate of neurologic defects in patients who survive. In children, recovery from the acute stage is sometimes followed by a permanent disorder of behavior, mental retardation, or epilepsy; paradoxically, most adults make good recoveries. The *cerebellitis* and acute ataxia that follow chickenpox and other infections are more benign and normally clear over several months as discussed further on.

Pathogenesis The pathogenesis of disseminated encephalomyelitis is still unclear despite its obvious association with viral infections. In the exanthem cases, a definite interval usually separates the onset of disseminated encephalomyelitis from the onset of the rash; also, the pathologic changes are quite different from those of viral infections and virus is rarely if ever recovered from the CSF or brains of patients with disseminated encephalomyelitis. For these reasons it is believed that the disorder represents an immune-mediated complication of infection rather than a direct infection of the CNS. However, as discussed in [Chap. 33](#), new molecular techniques have been able to detect fragments of DNA from varicella zoster virus, *Mycoplasma*, and other organisms, so that the question of pathogenesis cannot be answered with finality. Nevertheless, Waksman and Adams found the pathologic changes in these two circumstances—postinfectious demyelination and direct viral infection of the CNS—to be different.

A laboratory model of the disease, experimental allergic encephalomyelitis (EAE), has been produced by inoculating animals with a combination of sterile brain tissue and adjuvants. The experimental disease appears most commonly between the eighth and fifteenth days after sensitization (see below) and is characterized by the same perivenular demyelinative and inflammatory lesions that one observes in the human disease. Presumably the lesions are the result of a T-cell-mediated immune reaction to components of myelin or oligodendrocytes.

The notion that EAE and disseminated encephalomyelitis have a similar pathogenesis has received strong support from the observations of R. T. Johnson and colleagues. They studied 19 patients with postinfectious encephalomyelitis complicating natural measles virus infections. Early myelin destruction was demonstrated by the presence of MBP in the CSF, and lymphocyte proliferative responses to MBP were found in 8 of 17 patients tested. Similar responses were observed in patients with encephalomyelitis after rabies vaccine and after varicella and rubella virus infections, suggesting a common immune-mediated pathogenesis. Moreover, the patients with postmeasles encephalomyelitis showed a lack of intrathecal synthesis of antibody against measles virus, indicating that the neurologic disease was not dependent on virus replication within the CNS.

Clinical Features In the encephalitic form, as the acute infectious illness resolves or after a latency of several days or longer, there is the abrupt onset of confusion, somnolence, and often convulsions with headache, fever, and varying degrees of neck stiffness. Ataxia, myoclonic movements, and choreoathetosis are observed less frequently. In the more severe cases, stupor, coma, and at times decerebrate rigidity may occur in rapid succession. In the myelitic form (*postinfectious myelitis*, *acute transverse myelitis*), there is partial or complete paraplegia or quadriplegia, diminution or loss of tendon reflexes, sensory impairment, and varying degrees of paralysis of bladder and bowel. A syndrome that simulates anterior spinal artery occlusion (spastic paraplegia and loss of pain sensation below a level on the trunk, but tending to spare large-fiber sensibility) is not uncommon in our experience. Also, we have cared for a few patients with a limited sacral form of myelitis. Midline back pain may be a prominent symptom at the onset. There is generally no fever, and the peripheral white blood cell count is normal if the underlying infection has resolved. These features serve to distinguish a postinfectious disseminated encephalomyelitis from a viral meningoencephalitis. Either process may be associated with an aseptic meningitis.

In the case of postexanthem encephalomyelitis, the syndrome generally begins 2 to 4 days after the appearance of the rash. Usually the rash is fading and other symptoms are improving when the patient, usually a child, suddenly develops a recrudescence of fever, convulsions, stupor, and sometimes coma. Less commonly, the patient may develop hemiplegia or a virtually pure cerebellar syndrome, as noted below (particularly after chickenpox), and occasionally a transverse myelitis, sphincteric disturbance, or other signs of spinal cord involvement. Choreoathetotic movements are seen infrequently. In many cases the disease is much less severe and the patient suffers a transient encephalitic illness with headaches, confusion, and signs of meningeal irritation. The CSF usually shows an increase in lymphocytes and protein content, but these are highly variable, a few cases having no cells and others up to several hundred. The MRI scan shows bilateral confluent white matter lesions in both cerebral hemispheres early in the course of acute disseminated encephalomyelitis ([Fig. 36-4](#)); when these are large and numerous, the diagnosis is more certain, but some instances of viral encephalitis display subcortical changes in the white matter as well.

Figure 36-4 FLAIR MRI of acute (postinfectious) disseminated encephalomyelitis, showing numerous lesions of varying size throughout the white matter of both hemispheres.

A variant of postinfectious encephalomyelitis that involves solely or predominantly the cerebellum deserves special comment. Typically, a mild ataxia with variable corticospinal or other signs appears within days of one of the childhood exanthems as well as after Epstein-Barr virus, *Mycoplasma*, *Legionella*, and cytomegalovirus infections and after a number of vaccinations and nondescript respiratory infections. It is described in detail on page 797 because it has a close relationship to certain viruses, particularly varicella, suggesting that some if not most cases are due to an infectious meningoencephalitis. Others—for example, following mycoplasmal infection—occur after a long latency and show pathologic changes that are consistent with a postinfectious demyelination. Thus it appears that there may be two types of acute cerebellitis, one para- or postinfectious and the other due to a direct infection of the brain and meninges. The benign nature of the illness has precluded adequate pathologic examination, hence some of these statements are speculative.

Differential Diagnosis It must be re-emphasized that not all the neurologic complications of measles and other exanthems and acute viral infections are examples of postinfectious encephalomyelitis. As already noted, the illness is at times difficult to distinguish from viral meningoencephalitis. Infectious mononucleosis, herpes simplex, mycoplasmal infection, and other forms of encephalitis may all mimic the postinfectious variety. In some cases cerebrovascular disease (particularly thrombophlebitis), hypoxic encephalopathy, or acute toxic hepatoencephalopathy (Reye syndrome) is responsible for these complications. The Reye syndrome is usually not difficult to separate from postinfectious encephalomyelitis, even when it follows chickenpox or viral influenza, because of the normal CSF and high serum concentrations of liver enzymes and ammonia (see page 1187). In a child, the first attack of febrile seizures in the course of an exanthematous illness may raise the suspicion of encephalitis or postinfectious encephalomyelitis.

Postvaccinal Encephalomyelitis Since late in the nineteenth century, it has been known that a severe form of encephalomyelitis may complicate the injection of rabies vaccine (“neuroparalytic accident”). Until quite recently, the vaccine in common use consisted of killed virus that had been grown in rabbit brain tissue. Encephalomyelitis occurred in about 1 in 750 patients inoculated with this vaccine, and about 25 percent of cases with this complication proved fatal. Alternative vaccines, made from embryonated duck eggs (and later from human diploid cells) infected with fixed viruses, contain very little or no nerve tissue and are almost free of neurologic complications. In developing countries, where less expensive brain-based vaccines are still in use, neuroparalytic accidents continue to occur. The observations of Hemachudha and colleagues indicate that the altered immune mechanism that is operative in the neuroparalytic accident is the same as that in postmeasles encephalomyelitis and experimental allergic encephalomyelitis.

There are numerous recorded instances in which the old rabies vaccine (with neural tissue) induced an attack of what appeared to be MS. Shiraki and Otani reported such examples from Japan. The evolution of symptoms was subacute, over a period of 2 to 4 weeks, and the demyelinative lesions were macroscopic—up to 1 to 2.0 cm in diameter—but composed of confluent perivenous lesions. The disease could be reproduced in dogs—persuasive evidence that one form of acute MS is a variant of ADEM.

Encephalomyelitis following vaccination against smallpox has been known since 1860, having occurred about once in 4000 vaccinations. This disease is now of historical interest only, insofar as smallpox has disappeared as a human illness worldwide. In the United States, there have been no new cases for years, and smallpox vaccination is no longer included as part of immunization schedules.

The association of the neurologic disorder with vaccination usually leaves the diagnosis in little doubt, and the characteristic combination of encephalitic and myelitic features will help to distinguish the condition from meningitis, viral encephalitis, and poliomyelitis. Rarely, an atypical case may mimic any one of these disorders. On occasion, the disease may suggest involvement of nerve roots and peripheral nerves and may resemble acute inflammatory polyneuritis (Guillain-Barré syndrome). In fact, the rabies vaccine produced in South America from suckling mouse brain causes this type of peripheral nerve disease more often than encephalomyelitis.

The mortality rate of postvaccinal encephalomyelitis is high, between 30 and 50 percent. If recovery occurs, it may be surprisingly complete. However, a significant proportion of patients show residual neurologic signs, intellectual impairment, and behavioral abnormalities.

With regard to *treatment* of ADEM, the use of high-potency steroids appears to be the best choice, although controlled trials of this treatment have not been carried out. Steroids, given before or immediately upon the appearance of neurologic signs, modify the severity of experimental allergic encephalomyelitis; this provides the logic for their use in the human counterpart of this disease. However, the pathologic process cannot be altered once the first signs appear. Plasma exchange and intravenous immune globulin have also been anecdotally successful in some fulminant cases ([Kanter et al](#); [Stricker et al](#)) but not in four of our own.

Acute Necrotizing Hemorrhagic Encephalomyelitis (Acute Hemorrhagic Leukoencephalitis of Weston Hurst)

This, the most fulminant form of demyelinative disease, affects mainly young adults but also children. It is almost invariably preceded by a respiratory infection of variable duration (1 to 14 days), sometimes due to *M. pneumoniae* but more often of indeterminate cause. The neurologic symptoms appear abruptly, beginning with headache, fever, stiff neck, and confusion. These are followed in short order by signs of disease of one or both cerebral hemispheres and brainstem—focal seizures, hemiplegia or quadriplegia, pseudobulbar paralysis, and progressively deepening coma. Leukocytosis is usually present, sometimes reaching 30,000 cells per cubic millimeter, and the sedimentation rate is elevated. The CSF is often under increased pressure; cells vary in number from a few lymphocytes to a polymorphonuclear

pleocytosis of up to 3000 cells per cubic millimeter; red cells may be present in variable numbers; protein content is increased, but glucose values are normal. Diagnosis is greatly facilitated by CT scanning and MRI, which reveal bilateral but asymmetrical large, confluent edematous lesions in the cerebral white matter ([Fig. 36-5](#)). The size of the lesions and the extent of the surrounding edema are beyond what is seen in the usual case of postinfectious ADEM. Many cases terminate fatally in 2 to 4 days, but in others survival is longer. Patients with a similar clinical picture who are thought to have the same disease on the basis of brain biopsy examinations have recovered with almost no residual symptoms. In one of the fatal cases reported by [Adams et al](#), the illness evolved more slowly—over a period of 2 to 3 weeks—while another patient died with temporal lobe herniation within 12 h. A single recurrence of the disease was observed in one of our cases.

Figure 36-5 *Acute necrotizing hemorrhagic leukoencephalitis, mainly bifrontal.*

Brain abscess, subdural empyema, focal embolic encephalomalacia, and acute encephalitis due especially to type 1 herpes simplex virus are the important considerations in the differential diagnosis.

The *pathologic findings* are distinctive. On sectioning of the brain, the white matter of one or both hemispheres is seen to be destroyed almost to the point of liquefaction. The involved tissue is pink or yellow-gray and flecked with multiple small hemorrhages. Similar changes are often found in the brainstem and cerebellar peduncles and probably in the spinal cord (acute necrotizing myelitis and Devic disease). On histologic examination one finds widespread necrosis of small blood vessels and brain tissue around the vessels, with intense cellular infiltration, multiple small hemorrhages, and an inflammatory reaction in the meninges of variable intensity. The pathologic picture resembles that of disseminated encephalomyelitis in its perivascular distribution, with the added features of a more widespread necrosis and a tendency of lesions to form large foci in the cerebral hemispheres. The vascular lesions result in a characteristic exudation of fibrin into the vessel wall and surrounding tissue. It is possible that certain patients showing an explosive myelitic illness are suffering from a necrotizing lesion of similar type, but pathologic evidence in support of this view has been difficult to obtain. Fibrin exudation in an acute fatal myelitis was present in a case examined by [Adams and colleagues](#).

The *etiology* of this condition remains obscure, but the resemblance to other demyelinating diseases should be emphasized. The similarities of the histologic changes to those of disseminated encephalomyelitis, noted above, suggest that the two diseases are related forms of the same fundamental process. In fact, cases combining both types of pathologic change have been described ([Fisher et al](#)). The observations of Behan and colleagues—that the lymphocytes of a patient with postinfectious encephalomyelitis and of another patient with acute necrotizing hemorrhagic encephalitis underwent transformation to lymphoblasts in response to a pure encephalitogenic MBP—support the view that delayed hypersensitivity mechanisms are operative in both diseases. Earlier, Waksman and Adams had demonstrated that the vascular lesions of experimental allergic encephalomyelitis could be converted to those of necrotizing encephalomyelitis by inducing a Schwartzman reaction (by intravenous injection of meningococcal toxin). It is also noteworthy that among the small number of patients who have recovered from what appeared to be a typical necrotizing hemorrhagic encephalitis, a few have gone on to develop typical MS. These points of similarity are sufficient to suggest that corticosteroids should be used in the treatment of acute necrotizing hemorrhagic encephalopathy; in several personally observed patients, we had the impression that they produced a favorable result. The use of plasma exchange and intravenous immunoglobulin, as for acute disseminated encephalomyelitis, is being explored and has had success in single reported cases when instituted early.

[Chapter References](#)

Advances in biochemistry and molecular genetics have led to the discovery of such a large number of metabolic diseases of the nervous system that it taxes the mind just to remember their names. Standard laboratory methods—utilizing paper chromatography, gas-liquid chromatography, mass spectroscopy, and electron microscopy of tissue samples—are currently being supplemented by definitive nuclear and mitochondrial DNA gene analyses. Many of these techniques are now available in teaching hospitals and commercial laboratories and have significantly advanced our understanding of inherited disease. The problem for the neurologist is to know when and how to use them.

Since the causes and mechanisms of the diseases included in this chapter (and in several that follow) are increasingly being expressed in terms of molecular genetics, it seems appropriate, by way of introduction, to consider briefly some basic facts pertaining to the genetics of neurologic disease. A complete account of this subject may be found in the three-volume text edited by [Scriver and colleagues](#).

One must be reminded that the biochemistry of every human organism is unique and that every person, in some particular way, has an inborn tendency to develop certain diseases. This constitutional predisposition, or diathesis, lies in the DNA of the chromosomes of each cell. Knowledge of the molecular basis of the constitutional predisposition will ultimately provide the means of diagnosis, prevention, and care of most human diseases.

The diseases grouped in this chapter and the next represent four particular categories of genetic abnormality: (1) monogenic disorders that are determined by a single mutant gene and follow a mendelian pattern of inheritance; (2) multifactorial disorders, again following a mendelian pattern of inheritance but in which intrinsic (i.e., genetic) factors interact with exogenous environmental ones; (3) nonmendelian chromosomal aberrations, characterized by an excess, a lack, or a structural alteration of one or more of the 23 pairs of chromosomes (these are considered in the next chapter, with the developmental disorders); and (4) mitochondrial transmission of disease in a nonmendelian, mainly maternal pattern.

As to the frequency of these types of genetic abnormality (reported in the monograph of [Scriver et al](#)), 6 to 8 percent of diseases in hospitalized children are attributable to single gene defects and 0.4 to 2.5 percent to a chromosomal abnormality. Another 22 to 31 percent have a disease thought to be gene-influenced. In the general population, when multifactorial inheritance of late-onset diseases is included, the latter figure rises to about 60 percent. Mitochondrial inheritance is much less frequent and has unusual patterns of transmission, mostly through maternal lines.

The nervous system is more frequently affected by a genetic abnormality than any other organ system, probably because of the large number of genes implicated in its development (an estimated one-third of all the genes in the human genome). Approximately one-third of all inherited diseases are neurologic to some extent; if one adds the inherited diseases affecting the muscula-ture, skeleton, eye, and ear, the number rises to 80 to 90 percent.

Of the almost 6000 entities itemized in the 1998 edition of McKusick's catalogue of inherited diseases, about 500 are identified as enzymopathies, i.e., mendelian disorders with a demonstrated primary enzyme defect. The latter constitute only one-third of the known recessive (autosomal and X-linked) disorders. Most of the enzymopathies become manifest in infancy and childhood; only a few appear as late as adolescence or adult life. Many damage the nervous system so severely that survival to adult years and reproduction are impossible. As a group, these diseases—along with congenital anomalies ([Chap. 38](#)), birth injuries, epilepsy, disharmonies of development, and learning disabilities ([Chap. 28](#))—make up the bulk of the clinical problems with which the pediatric neurologist must contend.

Autosomal and Sex-Linked Patterns of Inheritance

Traditionally, the recognition of these broad categories of genetically determined diseases has rested on their pattern of occurrence in families, segregated according to mendelian inheritance into autosomal dominant, autosomal recessive, and sex-linked types. Mutations of nuclear DNA account for the majority of heritable autosomal and sex-linked diseases described in this chapter, and they are remarkably diverse in nature. Some are lethal and are therefore not transmitted to successive generations; others are less harmful and may conform to one of the classic mendelian patterns. The mutation may be large and may result in duplication or deletion of a major part of a chromosome or even of the entire genome (diploidy), or it may create a third copy of the entire complement of genes (triploidy). Other mutations are very small, involving only a single base pair (“point mutation”). Between these two extremes are deletions or duplications that include a portion of a gene, an entire gene, or contiguous genes.

Factors that are conducive to mutations are poorly understood. Increasing age of the parent is important in inducing some mutations; the size, structure, and placement of the gene on the chromosome are important in others. A mutation of the DNA of a germ cell leaves the somatic phenotype of the individual in whom it occurs normal, but it may have a devastating effect on the descendants. Conversely, a DNA mutation of a somatic cell affecting only part of the cell population may change the individual harboring it but may not be passed on to the descendants. Such an individual, with both normal cells and cells containing the mutant gene, is referred to as a *mosaic*. Mutations of somatic cells appear to be most relevant to cancer and aging.

In the monogenic inheritance of all three mendelian patterns, the mutation usually causes an abnormality of a single protein molecule. It may involve an enzyme, peptide hormone, immunoglobulin, collagen, or coagulation factor. Such abnormalities of single genes have been isolated in more than 300 diseases, but little is known of their products. About one-quarter of these diseases are apparent soon after birth and more than 90 percent by puberty. More than half of them affect more than one organ. As to their patterns of inheritance, of the 10 in every 1000 live births with genetic diseases, 7 are dominant, 2.5 are recessive, and the remainder are sex-linked.

Autosomal dominant genes usually cause manifest disease in heterozygotes, but variations in the size of the gene abnormality can produce any one of the several phenotypes. This poses a challenge to current clinical and pathologic classifications of disease. Moreover, an identical clinical syndrome may be traced to a gene on two different chromosomes. Even more surprising, an estimated 28 percent of all gene loci have polymorphic rather than monomorphic effects—that is, the same mutation has several different phenotypic expressions. Another problem is that of differentiating dominant from recessive inheritance. In small families, in which only one descendant is afflicted and the parent is seemingly normal, one may mistakenly conclude that the inheritance is recessive. Variable degrees of penetrance and expressivity are characteristic features of dominant patterns of inheritance but not of recessive ones. There is a general tendency for dominantly inherited disease to appear long after birth.

Autosomal recessive diseases, in contrast to dominant ones, occur only in the homozygous state (both alleles abnormal). They are characterized by a more uniform phenotypic expression and an onset soon after birth. The basic abnormality is more often an enzyme deficiency than an abnormality of some other protein.

In disorders of X-linked genes, in which the mutant gene affects mainly one sex, the female will suffer the same fate as the male if one X chromosome is inactivated in most cells during embryonic development ([Lyon phenomenon](#)). However, even if the abnormal X chromosome is not widely expressed, the female carrier may still exhibit minor abnormalities. In the latter case, sex-linked inheritance becomes difficult to distinguish from dominant inheritance. Also, sex linkage is deceptive when a disease is lethal to one sex. The biochemical abnormality has more often been one of a basic protein than an enzyme deficiency.

Multifactorial genetic diseases and their associated birth defects are by nature familial. They may present as constitutional disorders with gene abnormalities located on several chromosomes (polygenic). The precise number of such genes required to produce a given abnormality is not known, making the risk of inheritance difficult to calculate. Here also the relative contributions of “risk genes” and environmental influences are highly variable. The methodology for identifying this category of genetic disease has usually required the analysis of large families and the comparison between progeny living with their biologic parents and those adopted by normal families at an early age. Monozygotic and dizygotic twin comparisons provide essential information about “risk genes.”

The Genetics of Mitochondrial Disease

In the past several years, an entirely new type of genetic transmission relating to the DNA that lies in the mitochondria has been discovered. Mitochondria contain their own, extrachromosomal DNA, distinct from nuclear DNA. Mitochondrial DNA (“the other human genome”) is a double-stranded, circular molecule that encodes the protein subunits required mainly for translation of the proteins located on the mitochondrial inner membrane. Of the 37 mitochondrial genes, small in number by comparison with nuclear DNA, 13 partake in the cellular processes of oxidative phosphorylation and the production of adenosine triphosphate (ATP). A smaller number of genes in the cell's nucleus also code for some oxidative enzymes of the mitochondria, but their inheritance follows a mendelian pattern.

Each mitochondrion contains up to 10 DNA molecules, and each cell contains numerous mitochondria. Mutant genes may exist next to normal ones (*heteroplasmy*), a state that permits an otherwise lethal mutation to persist ([Johns](#)). The presence of either completely normal or completely mutant mitochondrial DNA is termed *homoplasmy*. The essential feature of mitochondrial genes and any of the mutations to which they are subject is that they are inherited from the maternal genome. Moreover, mitochondrial DNA does not recombine, thus permitting the accumulation of mutations through the maternal lines. Also, the replication and distribution of mitochondrial DNA during cell division does not follow the nuclear mitotic cycle. Instead, there are contributions during cell division from the genes of various mitochondria to the progeny of dividing cells. The combination of a heteroplasmic state and the capricious dispersion of mitochondria to daughter cells (replicative segregation) explains the variable expression of mitochondrial mutations in different regions of the nervous system as well as variations in the age of onset of the mitochondrial diseases.

The genetic error in each of the mitochondrial diseases is most often a single point mutation of an amino acid, but there may also be single or multiple deletions or duplications of mitochondrial genes that tend to be homoplasmic and do not conform to maternal inheritance or are caused by nuclear DNA defects. The Kearns-Sayre syndrome and some instances of progressive external ophthalmoplegia are of this type. Another of the general rules of mitochondrial inheritance is exemplified by an infantile myopathy (cytochrome oxidase deficiency) that is usually fatal but may also occur in a less severe form and have a later onset. In cases of earlier onset, there is less of the normal mitochondrial DNA than in the cases of later onset. It is important to note that about 85 percent of the protein components of the respiratory chain are coded in nuclear DNA and are then imported into the mitochondrion; as mentioned above, this allows for a mitochondrial disease with a mendelian pattern of inheritance rather than a maternal one.

Since the unique function of mitochondria is the production of ATP by oxidative phosphorylation, it is not surprising that most of the genes contained in mitochondria code for proteins in the respiratory chain. However, there is not always concordance between the error in the mitochondrial genome and the enzymatic defect that leads to disease. Of the five complexes that make up the respiratory chain, cytochrome-*c* oxidase (complex IV) is the one most often disordered, and its deficient function gives rise to lactic acidosis, a feature common to many of the mitochondrial disorders (see further on). In keeping with the mutable nature of this class of disorders, it is thought that some cases of complex IV defect are autosomally transmitted. Complex I defects, which originate in mitochondrial mutations, are seen in Leber optic atrophy. A more complete account of the disorders of the mitochondrial respiratory chain can be found in the recent review by [Leonard and Schapira](#).

As one would expect, aberrant function of the ubiquitous energy-producing mitochondria results in disease of many organs. Nevertheless, most of the mitochondrial disorders affect the nervous system prominently and at times exclusively. Certain fairly well defined conditions traceable to mitochondrial abnormalities include those with a particular change in muscle fibers termed “ragged red fibers” and others having in common a lactic acidosis. The most common of these syndromes are the so-called MELAS and MERFF syndromes (acronyms described further on), Leber hereditary optic atrophy, progressive external ophthalmoplegia, and the Leigh syndrome. These diseases and syndromes are described in the last part of this chapter.

Diagnostic Features of Hereditary Metabolic Diseases

In clinical practice, one should consider the possibility of a hereditary metabolic disease when presented with the following lines of evidence:

1. A neurologic disorder of similar type in a sibling or close relative
2. Recurrent nonconvulsive episodes of impaired consciousness
3. Some combination of unexplained spastic weakness, cerebellar ataxia, extrapyramidal disorder, deafness, or blindness
4. Progression of a neurologic disease measured in weeks, months, or a few years
5. Mental retardation in a sibling or close relative
6. Mental retardation in an individual, particularly if there are no congenital somatic abnormalities
7. Intractable seizures
8. Infantile spasms and progressive myoclonic seizures with microcephaly, in the absence of neonatal hypoxia-ischemia

In the face of such clinical information, one should request appropriate biochemical analyses of blood, urine, and cerebrospinal fluid (CSF); magnetic resonance imaging (MRI) of the brain; and, in certain instances, chromosome-genetic studies.

The array of available genetic and biochemical tests has made practical the mass screening of newborns for inborn metabolic defects. In addition, innovative tests have led to the discovery of a number of previously unknown diseases and have clarified the basic biochemistry of old ones. As a consequence, the neurologist's role is changing. No longer must he wait until a disease of the nervous system has declared itself by conventional symptoms and signs, by which time the lesion may have become irreversible. Now it is possible to find patients who, though asymptomatic, are at risk and to introduce dietary and other measures to prevent injury to the nervous system. This is especially important to families who have already had an affected infant. To assume this new responsibility intelligently requires some knowledge of genetics, biochemical screening methods, and public health measures.

The many clinical syndromes by which these inborn errors of metabolism declare themselves vary in accordance with the nature of the biochemical defect and the stage of maturation of the nervous system at which it acts. In phenylketonuria, for example, there is a specific effect on the cerebral white matter, mainly during the period of active myelination; once the maturational processes are complete, the biochemical abnormality becomes relatively harmless. Even more important is the level of function that has been achieved by the developing nervous system when the disease strikes. A derangement of function in a neonate or infant, in whom much of the cerebrum is not fully developed, is much less obvious than one in an older child; as the disease evolves, the clinical manifestations are always influenced by the continuing maturation of the untouched elements in the nervous system. The separation of metabolic-genetic from degenerative diseases (here accorded separate chapters) may disquiet the reader, for there are many seemingly illogical overlaps between the two groups. The current division is tenable only until such time as all the degenerative diseases will have been shown to have a metabolic basis.

Because of the overriding importance of the age factor and the tendency of certain pathologic processes to appear in particular epochs of life, it has seemed to the authors logical to group the inherited metabolic diseases not according to their major syndromes of expression, as we have done in other parts of the book, but in relation to the periods of life at which they are most likely to be encountered: the neonatal period, infancy (1 to 12 months), early childhood (1 to 4 years), late childhood, adolescence, and adult life. Only in the last two age periods do we return to a syndromic ordering of diseases.

In adopting this chronological subdivision, we realize that *certain hereditary metabolic defects that most typically manifest themselves at a particular period in life are not necessarily confined to that epoch and may appear, sometimes in variant form, at a later stage*. Such variations are noted at appropriate points in the discussion.

THE NEUROLOGY OF NEONATAL METABOLIC DISEASES

A small number of progressive metabolic diseases become manifest in the first few days of life. The importance of these diseases relates not to their frequency (they constitute only a small fraction of diseases that compromise nervous system function in the neonate) but to the fact that they must be recognized promptly if the infant is to be prevented from dying or from suffering a worse fate, that of a lifelong severe mental deficiency. This inherent threat introduces an element of urgency into neonatal neurology. Recognition of these diseases is also important for purposes of family and prenatal testing.

Two approaches to the neonatal metabolic disorders are possible—one, to screen every newborn, using a battery of biochemical tests of blood and urine, and the other, to undertake in the days following birth a detailed neurologic assessment that will detect the earliest signs of these diseases. Unfortunately, not all the biochemical tests have been simplified to the point where they can be adapted to a mass screening program, and many of the commonly used clinical tests at this age have yet to be validated as markers of disease. Moreover, the tests are costly, and practical issues such as cost-effectiveness insinuate themselves, to the distress of the pediatrician. The recent introduction of tandem mass spectrometry has allayed some of the latter concerns.

The Neurologic Assessment of Neonates with Metabolic Disease

As pointed out in [Chap. 28](#), the neonate's nervous system functions essentially at a brainstem-spinal level. The pallidum and visuomotor cortices are only beginning to be myelinated and their contribution to the totality of neonatal behavior cannot be very great. Neurologic examination, to be informative, must therefore be directed to evaluating diencephalic-midbrain, cerebellar–lower brainstem, and spinal functions. The integrity of these functions in the neonate is most reliably assessed by noting the following, as described in [Chap. 28](#):

1. Control of respiration and body temperature; regulation of thirst, fluid balance, and appetite-hypothalamus-brainstem mechanisms
2. Certain elemental automatisms, such as sucking, rooting, swallowing, grasping—brainstem- cerebellar mechanisms
3. Movements and postures of the neck, trunk, and limbs, such as reactions of support, extension of the neck and trunk, flexion movements and steppage—lower brainstem (reticulospinal), cerebellar, and spinal mechanisms
4. Muscle tone of limbs and trunk—spinal neuronal and neuromuscular function
5. Reflex eye movements—tegmental midbrain and pontine mechanisms (a modified optokinetic nystagmus can be recognized by the third day of life)
6. The state of alertness and attention (stimulus responsivity and capacity of the examiner to make contact) as well as sleep-waking and electroencephalographic patterns—diencephalic mechanisms
7. Certain reflexive reactions such as the startle (Moro) response and placing reactions of the foot and hand—upper brainstem–spinal mechanisms with cortical facilitation

Derangements of these functions are manifest as impairments of alertness and arousal, hypotonia, disturbances of ocular movement (oscillations of the eyes, nystagmus, loss of tonic conjugate deviation of the eyes in response to vestibular stimulation, i.e., to rotation of the upright infant), failure to feed, tremors, clonic jerks, tonic spasms, opisthotonos, diminution or absence of limb movements, irregular or chaotic breathing, hypothermia or poikilothermia, bradycardia, circulatory difficulties, poor color, and seizures.

In most instances of neonatal metabolic disease, the pregnancy and delivery proceed without mishap. Birth at full term is usual. The infant is of a size and weight expected for the duration of pregnancy, and there are no signs of a developmental abnormality (in a few instances the infant is somewhat small, and in G_{M1} gangliosidosis there may be a pseudo-Hurler appearance; see further on). Furthermore, function continues to be normal in the first few days of life. The first hint of trouble may be the occurrence of feeding difficulties: food intolerance, diarrhea, and vomiting. The infant becomes fretful and fails to gain weight and thrive—all of which should suggest a disorder of amino acid, ammonia, or organic acid metabolism.

The first definite indication of disordered nervous system function is likely to be the occurrence of seizures. These usually take the form of unpatterned clonic or tonic contractions of one side of the body or independent bilateral contractions, sudden arrest of respiration, turning of the head and eyes to one side, or twitching of the hands and face. Some of the seizures may become generalized. They occur singly or in clusters, and in the latter instance are associated with unresponsiveness, immobility, and arrest of respiration. While seizures are occurring, certain automatic activities such as sucking, grasping, steppage, and the Moro and support reactions are suppressed.

The other clinical abnormalities, according to authorities such as Prechtl and Beintema, can be subdivided roughly into three groups, each of which constitutes a kind of syndrome: (1) hyperkinetic-hypertonic, (2) apathetic-hypotonic, or (3) unilateral or hemisyndromic. Prechtl and Beintema, from a study of more than 1500 newborns, found that if clinical examination consistently discloses any one of the three syndromes, the chances are two out of three that by the seventh year the child will be abnormal neurologically. They found also that certain neurologic signs—such as facial palsy, lack of grasping, excessive floppiness, and impairment of

sucking—while sometimes indicative of serious disease of the nervous system, are less dependable; also, being rare, these signs will identify but few brain-damaged infants. It is not the single neurologic sign but groups of them that are held to be the most reliable indices of brain abnormality, and the three syndromes mentioned above are the important ones, even though their anatomic and physiologic bases are not completely known.

In our observations of the neonatal metabolic diseases, we have endeavored to determine if particular ones consistently manifest themselves by one or another of the three syndromes; this we are able to affirm to some degree. In cases of hypocalcemia-hypomagnesemia, the hyperkinetic-hypertonic syndrome prevails. Although most of the other diseases tend to induce the apathetic-hypotonic state, the hyperactive-hypertonic syndrome may represent the initial phase of the illness and always carries a less ominous prognosis than the apathetic-hypotonic state, which represents a more severe and potentially dangerous condition regardless of cause. We have been least confident in the recognition of the third putative group of unilateral abnormalities in the metabolic diseases. Even more discouraging has been the frequent overlapping of the two other syndromes and the fact that seizures may occur in all of them. The anatomic correlate for some of these neurologic abnormalities can be provided by MRI. Clearly what is needed is a new neonatal neurologic semiology utilizing every possible type of stimulus-response test, including visual, auditory, and somatosensory evoked potentials; also needed are ways of accurately quantifying more of the natural activities of this age period. Even the brain death syndrome, in which all brainstem-spinal reflexes are abolished, has not been fully defined in the neonate ([Adams et al](#)).

The Neonatal Metabolic Diseases and Their Estimated Frequency

In New England, screening of all newborns for metabolic disorders has been in operation for almost 40 years. Current data on the diseases with neurologic implications have been collated by our colleague, H. L. Levy, and are summarized in [Table 37-1](#). Some of these disorders can be recognized by simple color reactions in the urine; these are listed in [Table 37-2](#).

Disease	Total screened	Total detected	Frequency
Congenital hypothyroidism	5,105,000	140	1:1,500
Phenylketonuria	4,718,700	176	1:16,000
Arylsul TNU	4,718,700	200	1:17,000
Maple syrup disorder	1,603,501	40	1:22,000
Mucopolysaccharidosis	1,603,501	30	1:27,000
Methylmalonic acidemia	1,603,501	10	1:50,000
Galactosemia	5,018,714	43	1:42,000
Argininosuccinic acidemia	1,603,501	13	1:80,000
Biotinidase deficiency	4,719,123	14	1:340,000
Mucopolysaccharidosis	5,390,000	16	1:330,000
Maple syrup urine disease	4,719,173	10	1:470,000
Phenylalanine deficiency	1,603,501	3	1:700,000
Hypoparathyroidism (type II)	1,603,501	2	1:800,000
Short-chain and long-chain fatty acid deficiency	1,603,501	1	1:1,000,000

Source: Data compiled by Henry J. Levy, MD, and Charles Williams III.

Table 37-2 Urinary screening tests for metabolic defects

To this group should be added the inherited hyperammonemic syndromes and vitamin-responsive aminoacidopathies (such as pyridoxine dependency and biopterin deficiency) as well as certain nonfamilial metabolic disorders that make their appearance in the neonatal period—hypocalcemia, hypothyroidism and cretinism, hypomagnesemia with tetany, and hypoglycemia.

It is important to note that the three most frequently identified hereditary metabolic diseases— phenylketonuria (PKU), hyperphenylalaninemia, and congenital hypothyroidism—do not become clinically manifest in the neonatal period and are therefore discussed in a later portion of this chapter and in [Chap. 40](#) (in the discussion of congenital hypothyroidism, page 1200). This is fortunate, for it allows time to introduce preventive measures before the first symptoms appear. A number of others, which can be recognized either by screening or by early signs, are synopsized below.

Vitamin-Responsive Aminoacidopathies Included under this heading is a group of diseases that respond not to dietary restriction of a specific amino acid but to the oral supplementation of a specific vitamin. Some 30 vitamin-responsive aminoacidopathies are known (the more common ones are listed in [Table 41-3](#)), and many of them result in injury to the central nervous system. Pyridoxine dependency is the classic example. This is a rare disease, inherited as an autosomal recessive trait. It is characterized by the early onset of convulsions, sometimes in utero; failure to thrive; hypertonia-hyperkinesia; irritability; tremulous movements (“jittery baby”); exaggerated auditory startle (hyperacusis); and later, if untreated, by psychomotor retardation. The specific laboratory abnormality is an increased excretion of xanthurenic acid in response to a tryptophan load. There are decreased levels of pyridoxal-5-phosphate and gamma-aminobutyric acid (GABA) in brain tissue. The neuropathology has been studied in only a few cases. In one of our patients, a 13 1/2-year-old boy with mental retardation, pale optic discs, and spastic legs, the brain weight was 350 g below normal. There was a decreased amount of central white matter in the cerebral hemispheres and a depletion of neurons in the thalamic nuclei and cerebellum, with gliosis ([Lott et al](#)). The administration of 50 to 100 mg of vitamin B₆ suppresses the seizure state, and daily doses of 40 mg permit normal development.

Biopterin Deficiency Some patients with increased concentrations of serum phenylalanine in the neonatal period are unresponsive to measures that lower phenylalanine. They are usually found to have a defect in biopterin metabolism. If this condition is unrecognized and not treated promptly, seizures of both myoclonic and later grand mal types combined with a poor level of responsiveness and generalized hypotonia develop. Swallowing difficulty is another prominent symptom. Within a few months, developmental delay becomes prominent. Unlike in PKU, phenylalanine hydroxylase enzyme levels are normal, but there is a lack of tetrahydrobiopterin, which is a cofactor of phenylalanine hydroxylase. Treatment consists of administration of tetrahydrobiopterin in a dosage of 7.5 mg/kg per day in combination with a low-phenylalanine diet. It is important to recognize this condition early in life by the measurement of urine pterins and to institute appropriate therapy before irreversible brain injury occurs.

Galactosemia Inheritance of this disorder is autosomal recessive. The biochemical abnormality consists of a defect in galactose-1-phosphate uridyl transferase (GALT), the enzyme that catalyzes the conversion of galactose-1-phosphate to uridine diphosphate galactose. Several forms of galactosemia have been described, based on the degree of completeness of the metabolic block. In the classic (severe) form, the onset of symptoms is in the first days of life, after the ingestion of milk; vomiting and diarrhea are followed by a failure to thrive. Drowsiness, inattention, hypotonia, and diminution in the vigor of neonatal automatisms then become evident. The fontanelles may bulge, the liver and spleen enlarge, the skin becomes yellow (in excess of neonatal jaundice), and anemia develops. Rarely there is thrombocytopenia with cerebral bleeding. Cataracts may form due to the accumulation of galactitol in the lens. Surviving infants show retarded psychomotor development, visual impairment, and residual cirrhosis, sometimes with splenomegaly and ascites. In one such patient, who died at 8 years, the main change in the brain was slight microcephaly with fibrous gliosis of the white matter and some loss of Purkinje and granule cells in the cerebellum, also with gliosis ([Crome](#)). The diagnostic laboratory findings are an elevated blood galactose level, low glucose, galactosuria, and deficiency of GALT in red and white blood cells and in liver cells.

The treatment is essentially dietary, using milk substitutes; if this is instituted early, the brain is protected from injury.

A late-onset neurologic syndrome has also been observed by [Friedman and colleagues](#) in galactosemic patients who survived the infantile disease. By late adolescence, they are found to be subnormal intellectually and socially maladjusted; some have shown cerebellar ataxia, dystonia, and apraxia. One of these patients was middle-aged.

Organic Acidurias of Infancy These have been divided into ketotic and nonketotic types. Among the *ketotic types*, the main one is *propionic acidemia*. It is an autosomal recessive disease due to a primary defect in organic acid metabolism that is expressed clinically by episodes of vomiting, lethargy, coma, convulsions, hypertonia, and respiratory difficulty. The onset is in the neonatal or early infantile period; in time, psychomotor retardation becomes evident. Death usually occurs within a few months. Propionic acid, glycine, various forms of fatty acids, and butanone are elevated in the serum. High protein intake induces ketotic attacks.

A number of other ketotic acidurias also occur in infancy. The most important of these are *methylmalonic acidemia*, *isovaleric acidemia*, *beta-keto acidemia*, and *lactic acidemia*. Each of these disorders can present with profound metabolic acidosis and intermittent lethargy, vomiting, tachypnea, and coma, with early death in about half the patients and developmental retardation in those who survive. Rare subtypes of methylmalonic acidemia respond to vitamin B₁₂. Isovaleric acidemia is characterized by a striking odor of stale perspiration, which has given it the sobriquet “sweaty foot syndrome.” Marked restriction of dietary protein (specifically leucine) may prevent attacks of ketoacidosis and permit relatively good psychomotor development. Numerous metabolic defects, most commonly of pyruvate decarboxylase and pyruvate dehydrogenase, are responsible for the accumulation of lactic and pyruvic acids. The enzymatic defect of isovaleric acidemia has also been demonstrated in a recurrent form of episodic cerebellar ataxia and athetosis and in a persistent form in mitochondrial encephalopathies (Leigh disease), as described further on in this chapter.

Type II glutaric acidemia has also been observed in the neonatal period and causes episodes of acidosis with vomiting and hyperglycemia. Multiple congenital anomalies of brain and somatic structures and cardiomyopathy are conjoined. A diet low in the specific toxic amino acid and supplements of carnitine and riboflavin are recommended, but the effects are unclear.

In the *nonketotic form of hyperglycinemia*, there are high levels of glycine but no acidosis. The notable diagnostic finding is an elevation of the CSF glycine, several times higher than that of the blood. The effects on the nervous system are more devastating than in the ketotic form. In reported cases (the authors have seen several), the neonate is hypotonic, listless, and dyspneic, with dysconjugate eye movements, opisthotonic posturing, myoclonus, and seizures. A few such neonates survive to infancy but are extremely retarded and helpless. Spongy degeneration of the brain has been reported both in this disease and in the ketotic form ([Shuman et al](#)). No treatment has been effective in severe cases. In an atypical milder form with neurologic abnormalities that appear in later infancy or childhood, reduction of dietary protein and administration of sodium benzoate in doses up to 250 mg/kg per day have been beneficial. The use of dextromethorphan, which blocks glycine receptors, is effective in preventing seizures and coma.

Inherited Hyperammonemias These are a group of six diseases caused by inborn deficiencies of the enzymes of the Krebs-Henseleit urea cycle; they are designated as *N-acetyl glutamate synthetase*, *carbaryl phosphate synthetase* (CPS), *ornithine transcarbamylase* (OTC), *argininosuccinic acid synthetase* (*citrullinemia*), *argininosuccinase deficiency*, and *arginase deficiency*. Hyperornithemia-hyperammonemia-homocitrullinemia (HHH) and intrinsic protein intolerance are closely related disorders. A detailed account of these inherited hyperammonemic syndromes is contained in the review by [Brusilow and Horwich](#).

The pattern of inheritance of each of these disorders is autosomal recessive except for OTC deficiency, which is X-linked dominant. Their clinical manifestations are a common expression of an accumulation of ammonia or of urea cycle intermediates in the brain; they differ only in severity, in accordance with the degree of completeness of the enzymatic deficiency and with the age of the affected individual. The one exception is arginase deficiency, which commonly presents during later childhood as a progressive spastic paraplegia with mental retardation. Clinically it has been convenient to divide the hyperammonemias into two groups—one that presents in the neonatal period and another that presents in the weeks or months thereafter. This division is somewhat artificial, the clinical presentation being more in the nature of a continuous spectrum governed by the biologic factors mentioned above.

In the most severe forms of the hyperammonemic disorders, the infants are asymptomatic at birth and during the first day or two of life, after which they refuse their feedings, vomit, and rapidly become inactive and lethargic, soon lapsing into an irreversible coma. Profuse sweating, focal or generalized seizures, rigidity with opisthotonos, and hypothermia and hyperventilation have been observed in the course of the illness. These symptoms constitute a medical emergency, and even with measures to reduce ammonium, the disease is usually fatal.

In less severely affected infants, hyperammonemia develops some months later, when protein feeding is increased. There is a failure to thrive, and attempts to enforce feeding or periods of constipation (both of which increase ammonia production in the bowel) may be accompanied by bouts of vomiting, hyperirritability, and screaming. Respiratory alkalosis is a consistent feature. Other manifestations are episodes of alternating hypertonia and hypotonia, seizures, ataxia, blurred vision, and periods of confusion, stupor, and coma. During episodes of stupor, often precipitated by dehydration, an alimentary protein load, or minor surgery, brain edema may be seen by CT and MRI; with repeated relapses, the brain edema gives way to atrophy, which appears as symmetrical areas of decreased attenuation in the cerebral white matter. Between attacks, some patients with partial deficiency may be normal or show only a slight hyperbilirubinemia ([diMagno et al](#), [Rowe et al](#)). With decompensation, the bilirubin rises, as does ammonia, but neither reaches exceedingly high levels. After repeated attacks, signs of motor and mental retardation become evident, and the patient is vulnerable to recurrent infections. Two adult male patients in our care, who were married (azoospermia is common) and working at technically demanding jobs, came to medical attention because of bouts of visual blurring followed by stupor that evolved over hours. They had displayed an aversion to protein and milk products as children; in later life, after meals high in protein, they became encephalopathic, one with severe brain swelling ([Shih et al](#)). There are few phenotypic differences among the late-onset hyperammonemias except for *argininosuccinic aciduria*, in which excessive dryness and brittleness of the hair (trichorrhexis nodosa) are notable features.

Diagnosis is established by the finding of hyperammonemia, often as high as 1500 mg/dL. The precise biochemical diagnosis requires testing of blood and urine for amino acids or assays for specific enzymes in red cells, liver, or jejunal biopsies. The primary hyperammonemias must be distinguished from the organic acidurias, including *methylmalonic aciduria* (see above), in which hyperammonemia can occur as a secondary metabolic abnormality.

In all the neonatal hyperammonemic diseases, the liver is often enlarged and liver cells appear to be inadequate in their metabolic functions, but how the enzymatic deficiencies or other disorders of amino acid metabolism affect the brain remains uncertain. It must be assumed that in some the saturation of the brain by ammonia impairs the oxidative metabolism of cerebral neurons, and when blood levels of ammonium increase (from protein ingestion, constipation, etc.), episodic coma or a more chronic impairment of cerebral functions occurs—as it does in adults with cirrhosis of the liver and portal-systemic encephalopathy. When the hyperammonemia is abrupt in onset and severe, the resulting combination of encephalopathy, brain swelling, and respiratory alkalosis simulates the *Reye syndrome*. As in all forms of liver disease, valproic acid and other hepatic toxins may cause hepatic coma by further impairing the urea cycle enzymes. In a few cases, a hyperammonemic disease has come to light after the administration of one of these drugs.

Ornithine Transcarbamylase Deficiency and Argininosuccinic Aciduria These are episodic diseases in which hyperammonemia develops usually later in childhood, but they may become manifest in the neonatal period. The main clinical features are episodic stupor, ataxia, and seizures. They are discussed above.

Treatment of the Hyperammonemic Syndromes The *treatment* of acute hyperammonemic syndromes is directed to the lowering of ammonium by hemodialysis, exchange transfusions, and administration of arginine and certain organic acids. With subsidence of the acute symptoms, a systematic form of management (as outlined by [Brusilow et al](#) and by [Msall et al](#)) should be undertaken. Sodium benzoate should be given in doses up to 250 mg/day, supplemented by sodium phenylacetate or sodium phenylbutyrate, which on theoretical grounds should divert nitrogen from the ureagenesis cycle. Arginine (50 to 150 mg/kg) should be added to the diet, since a deficiency of this substance may be responsible for the mental retardation and skin rashes. In more chronic cases, treatment consists of decreasing the ammonium load (by dietary protein restriction and by administration of oral antibiotics and lactulose). In infants with inborn errors of ureagenesis, there is a constant danger of recurrent episodes of hyperammonemia and coma, particularly in response to infections. In a few instances, careful management of the metabolic error has resulted in normal psychomotor development.

Liver transplantation may prove to be a therapeutic option.

Branched Chain Aminoacidopathies (Maple Syrup Urine Disease and Its Phenotypes) These conditions are caused by a deficiency of α -ketoacid dehydrogenase, resulting in the accumulation of the branched chain amino acids leucine, isoleucine, and valine and the corresponding branched chain α -keto acids. Maple syrup urine disease may be taken as the prototype. The pattern of inheritance is autosomal recessive. The infant appears normal at birth, but toward the end of

the first week, intermittent hypertonicity, opisthotonos, and respiratory irregularities appear. These are followed by diminished neonatal automatisms, convulsions, severe ketoacidosis, and often coma and death toward the end of the second to fourth week. This disease is one of the causes of the malignant epileptic syndrome of early infancy ([Brett](#)). Milder forms of the disease present with feeding difficulties that begin somewhat later in the early infantile period, followed by recurrent infections, episodic acidosis, coma, and retarded psychomotor development. Some of these patients, toward the end of the first year, may become quadriparetic or ataxic; or there may be only a nonspecific mental retardation. The urine smells like maple syrup and gives a positive test for 2,4-dinitrophenylhydrazine (DNPH).

Other important laboratory findings are increased plasma and urine concentrations of leucine, isoleucine, valine, and keto acids. Secondary accumulation of a derivative of α-hydroxybutyric acid probably accounts for the maple syrup odor. The neuropathologic findings are uncertain. In the first acute case described, only interstitial edema was observed; in more chronic cases, pallor and loss of myelin and gliosis of the cerebral white matter are found. Treatment by restriction of foods containing branched chain amino acids (leucine, isoleucine, and valine) allows reasonably normal mental development, but only if such restriction is begun in the neonatal period. A thiamine-responsive variant with a slightly different pattern of ketoacids has been described by [Prensky and Moser](#).

Other Organic Acidemias In addition to maple syrup urine disease, there are a number of other metabolic disturbances, some of them of mitochondrial origin, that appear in the neonatal period or later and are marked by an organic acidemia. If they are severe, the infant manifests a metabolic (lactic) acidosis soon after birth, with lethargy, feeding problems, rapid respirations, and vomiting. Or there may be irritability, jerky limb movements, and hypertonia. Later presentations take the form of feeding difficulties, repeated vomiting, hypotonia, and failure to thrive; with the passage of time, psychomotor retardation and drug-resistant seizures become evident. Metabolic stress—e.g., intercurrent infection or surgical procedures—may precipitate an episode of lactic or ketoacidosis.

Biochemical studies may disclose a biotinidase deficiency, methylmalonic aciduria, glutaric acidemia, methylglutagonic acidemia, or any number of other organic acid abnormalities. The precise abnormality is determined by measuring enzyme activity in white blood cells or cultured skin fibroblasts. As remarked above, some of these enzymes act in conjunction with a specific vitamin cofactor, so that exact diagnosis is imperative. The biotinidase deficiency may respond to 10 mg of biotin per day; the methylmalonic acidemia to 1 to 2 mg of vitamin B₁₂ per day; maple syrup urine disease to 10 to 20 mg of thiamine per day; and glutaric acidemia types I and II to 300 mg of riboflavin per day. The administration of carnitine may increase the elimination of toxic metabolites.

The care of these patients during an acute illness is of extreme importance. See [Lyon and colleagues](#) for a more complete description.

Sulfite Oxidase Deficiency (See also page 1038) This is an extremely rare disorder of sulfur metabolism, manifest clinically during the neonatal period by seizures, reduced level of responsivity, and spasms with opisthotonos. With survival into infancy, episodic confusion and stupor give way to seizures, mental retardation, and ataxia. In one of our cases described by [Shih and colleagues](#), a stroke-like syndrome of hemiplegia and aphasia appeared during a relapse at the age of 4.5 years, and in a Belgian case, subluxation of the lenses and choreoathetosis appeared at 8 months of age.

Shih and colleagues have identified sulfite, thiosulfite, and S-sulfocysteine in the urine. Cerebral atrophy with loss and destruction of white matter and gray matter (cerebral cortex, basal ganglia, and cerebellar nuclei) has been observed in one postmortem examination. Increasing the intake of molybdenum or lowering the dietary intake of sulfur amino acids are therapeutic possibilities, not yet fully tried.

Diagnosis of Neonatal Metabolic Diseases

An important clue, of course, is provided by the history of a neonatal disease or unexplained death earlier in the same sibship or in a male maternal relative. A history that protein foods are rejected by the infant, or even a history among relatives of a dislike of protein or feeding difficulties in infancy, should raise the suspicion of an inherited hyperammonemic disorder or an organic acidemia. Measurements of blood ammonia and lactate and of the urine for ketones and reducing substances are the key laboratory tests. A wide-spectrum screening program may disclose a biochemical abnormality; this is the optimal state of affairs, especially when this type of screening provides the information before symptoms appear.

A number of nonhereditary metabolic diseases must be distinguished from the hereditary ones in this period of life. *Hypocalcemia* is one of the most frequent causes of neonatal seizures; tetany, spasms, and tremulous movements are usually present. Its cause is unknown, but the disorder is easily corrected, with excellent prognosis. Symptomatic *hypoglycemic* reactions are frequent in neonates. Premature infants are the most susceptible. With blood sugar levels of less than 30 mg/dL in the mature infant and less than 20 mg/dL in the premature, there are seizures, tremulousness, and drowsiness. Maternal toxemia and diabetes mellitus also predispose to hypoglycemia. Other causes of hypoglycemia are adrenal insufficiency, galactosemia, an idiopathic pancreatic islet-cell hyperplasia, the treatable fatty acid beta oxidation disorders, and the recently reported congenital deficiency of CSF glucose transport—causing persistent hypoglycorachia and refractory seizures unless blood glucose levels are kept high. The damaging effects of untreated hypoglycemia have been well documented by [Koivisto and colleagues](#). There is also a recently recognized disorder of CSF serine transport causing failure to thrive, severe developmental disability and spasticity, and intractable epilepsy. Diagnosis is made by measuring CSF amino acids; treatment is with high-dose oral serine. *Cretinism* and *idiopathic hypercalcemia* are other recognizable entities at this age period.

Aicardi has described a neonatal myoclonic syndrome and Ohtahara, a malignant neonatal seizure disorder. In some of the cases, the neonatal syndrome merged later with the West type of infantile spasm disorder and the Lennox-Gastaut syndrome. Some of the cases had developmental abnormalities of the cerebrum, and severe mental retardation was the outcome. In other cases of this type, a familial coincidence was a feature; a metabolic defect was suspected in these cases but never proved.

The hereditary metabolic diseases must also be distinguished from a number of other catastrophic disorders that occur at or soon after birth, such as asphyxia, perinatal ventricular hemorrhage with the respiratory distress syndrome of hyaline membrane disease, other hypotensive-hypoxic states, erythroblastosis fetalis with kernicterus, neonatal bacterial meningitis, meningoencephalitis (herpes simplex, cytomegalic inclusion disease, listeriosis, rubella, syphilis, and toxoplasmosis), and hemorrhagic disease of the newborn. These are described in [Chap. 38](#).

THE HEREDITARY METABOLIC DISEASES OF INFANCY

The hallmark of all the hereditary metabolic diseases is *psychosensorimotor regression*. However, those that have their onset in the first year of life pose extraordinary problems in neurologic diagnosis. If the onset is in the first postnatal months, before the infant has had time to develop the normal complex repertoire of behavior, the first signs of disease may take the form of subtle delays in maturation rather than of psychomotor regression. Departures from normalcy include a lack of interest in the surroundings, a lack of visual engagement, continued poor head control, an inability to sit up at the usual time, poor hand-eye coordination, and persistence of infantile automatisms. Of course, embryologic maldevelopment of the brain may have similar effects, and systemic diseases and other visceral malformations—such as cystic fibrosis, renal disease, biliary atresia and congenital heart disease, chronic infection, malnutrition, and seizures (with drug therapy)—may appear to impede psychomotor development. Diagnosis becomes somewhat easier in the second half of the first year, especially if development in the first half had proceeded normally. Then an observant mother can perceive a loss of certain early acquisitions, attesting to the progressive nature of a disease.

The most distinctive members of this category of neurologic disease are the *leukodystrophies* and the so-called *lysosomal storage diseases*. The leukodystrophies are a group of inherited metabolic diseases of the nervous system, characterized by progressive, symmetrical, and usually massive destruction of the white matter of the brain and sometimes of the spinal cord; each type of leukodystrophy is distinguished by a particular abnormal product of degeneration of myelinated fibers. In the *lysosomal storage diseases*, there is a genetic deficiency of the enzymes (usually one or more of the acid hydrolases) necessary for the degradation of specific glycosidic or peptide linkages in the intracytoplasmic lysosomes, causing nerve cells to become engorged with material that they would ordinarily degrade. These metabolites eventually damage the nerve cell or myelin sheath. Most of these diseases are classed as sphingolipidoses. It was Brady in 1966 who made the observation that in each of these disorders an increased quantity of sphingolipid accumulated in the brain and other tissues. The sphingolipids are a class of intracellular lipids that all have ceramide as their basic structure, but each has a different attached oligosaccharide or phosphorylcholine. The rate of synthesis of the sphingolipids is normal and their accumulation results from a defect of a specific lysosomal enzyme that normally degrades each of the glycoproteins, glycolipids, and mucopolysaccharides by removing a monosaccharide or sulfate moiety. It is the type of enzyme deficiency and accumulated metabolite, as well as the tissue distribution of the undegradable substrate, that impart a distinctive biochemical and clinical character to each of the diseases in this category.

The concept of lysosomal storage diseases, introduced by [Hers in 1965](#), excited great interest among neurologists because it provided the potential for prenatal diagnosis and detection of carriers. The diagnosis of this group of diseases has also been facilitated by the use of CT scanning, MRI, and evoked response techniques, which confirm the existence of leukodystrophies, and by the electron microscopic examination of skin, rectal, or conjunctival biopsies, circulating lymphocytes, and cultured amniotic fluid cells, which discloses the lysosomal storage material in nonneural cells. The activity of most lysosomal enzymes can be

progressive spinal muscular atrophy in juveniles and young adults, due presumably to widespread involvement of spinal motor neurons (see further on).

Tay-Sachs disease is untreatable but can be prevented by testing all individuals of Jewish origin for the recessive trait. Since this screening was instituted at the E. K. Shriver Center in 1968, there has not been a single case known to us in Massachusetts.

In *Sandhoff disease*, which affects non-Jewish infants, there is a deficiency of both hexosaminidase A and B, moderate hepatosplenomegaly, and coarse granulations in bone marrow histiocytes. The clinical and pathologic picture is the same as in Tay-Sachs disease except for the additional signs of visceral lipid storage. Occasionally these visceral organs are not enlarged.

Infantile Gaucher Disease (Type II Neuronopathic Form, Glucocerebrosidase Deficiency)

This is an autosomal recessive disease without ethnic predominance, first described by Gaucher in 1882. The onset of the neuronopathic form is usually before 6 months and frequently before 3 months. The clinical course is more rapid than that of Tay-Sachs disease (most patients with infantile Gaucher disease do not survive beyond 1 year and 90 percent, not beyond 2 years). There is rapid loss of head control, of ability to roll over and sit, and of purposeful movements—along with apathy, irritability, frequent crying, and difficulty in sucking and swallowing. In some cases progression is slower, with acquisition of single words by the first year, bilateral corticospinal signs (Babinski signs and hyperactive tendon reflexes), *persistent retroflexion of the neck*, and *strabismus*. Laryngeal stridor and trismus, diminished reaction to stimuli, smallness of the head, rare seizures, normal optic fundi, *enlarged spleen* and slightly enlarged liver, poor nutrition, yellowish skin and scleral pigmentation, osteoporosis, vertebral collapse and kyphoscoliosis, and sometimes lymphadenopathy complete the clinical picture. The CSF is normal; the EEG is abnormal but nonspecifically so.

The important laboratory findings are an *increase in serum acid phosphatase and characteristic histiocytes (Gaucher cells)* in marrow smears and liver and spleen biopsies. A *deficiency of glucocerebrosidase* in leukocytes and hepatocytes is diagnostic; glucocerebroside accumulates in the involved tissues. The characteristic pathologic feature is the Gaucher cell, 20 to 60 μm in diameter, with a wrinkled appearance of the cytoplasm and eccentricity of the nucleus. These cells are found in the marrow, lungs, and other viscera; neuronal storage is seldom evident. In the brain, the main abnormality is a loss of nerve cells, particularly in the bulbar nuclei, and a reactive gliosis.

Type I Gaucher disease, by contrast, is nonneuronopathic and relatively benign. A type III Gaucher disease is neuropathic. It expresses itself in late childhood or adolescence by a slowly progressive mental decline, seizures, and ataxia, and, later, by spastic weakness and splenomegaly. Vision and retinae remain normal. Highly diagnostic is a defect in voluntary lateral gaze, with full movements on the oculocephalic (“doll’s head”) maneuver. These signs help to differentiate Gaucher from Niemann-Pick disease, in which vertical eye movements are lost. The nucleotide sequence of the cloned glucocerebrosidase of type I Gaucher disease was found by [Tsuji and associates](#) to be different from that of types II and III. There is no treatment for the latter types.

Infantile Niemann-Pick Disease (Sphingomyelinase Deficiency)

This is also an autosomal recessive disease. Two-thirds of the affected infants have been of Ashkenazi Jewish parentage. The onset of symptoms in the usual type A disease is between 3 and 9 months of age, frequently with marked *enlargement of liver, spleen, and lymph nodes and infiltration of the lungs*; rarely there is jaundice and ascites. Cerebral abnormalities are definite by the end of the first year, often earlier. The usual manifestations are loss of spontaneous movements, lack of interest in the environment, axial hypotonia with bilateral corticospinal signs, blindness and amaurotic nystagmus, and a macular cherry-red spot (in about one-quarter of the patients). Seizures may occur but are relatively late. There is no acoustic myoclonus, and head size is normal or slightly reduced. Loss of tendon reflexes and slowed conduction in peripheral nerves have been reported but are rare. Protuberant eyes, mild hypertelorism, slight yellowish pigmentation of oral mucosa, and dysplasia of dental enamel have also been reported but are rare. Most patients succumb to an intercurrent infection by the end of the second year.

Vacuolated histiocytes (“foam cells”) in the bone marrow and vacuolated blood lymphocytes are the important laboratory findings. A *deficiency of sphingomyelinase* in leukocytes, cultured fibroblasts, and hepatocytes is diagnostic. Neurons are decreased in number, and many of the remaining ones are pale and ballooned, and have a granular cytoplasm. The most prominent neuronal changes are seen in the midbrain, spinal cord, and cerebellum. The white matter is little affected. The retinal nerve cell changes are similar to those in the brain. The foamy histiocytes (Niemann-Pick cells) that fill the viscera contain sphingomyelin and cholesterol; the distended nerve cells contain mainly sphingomyelin.

There are also less severe late infantile and juvenile forms of Niemann-Pick disease, types C and D. These are discussed in a later section of this chapter.

Infantile, Generalized G_{M1} Gangliosidosis (Type I, b-Galactosidase Deficiency, Pseudo-Hurler Disease)

This is probably an autosomal recessive disease without ethnic predominance. The infants appear abnormal at birth. They have *dysmorphic facial features*, like those of the mucopolysaccharidoses: depressed and wide nasal bridge, frontal bossing, hypertelorism, epicanthi, puffy eyelids, long upper lip, gingival and alveolar hypertrophy, macroglossia, and low-set ears. These features, with the bone changes mentioned below, account for the term “pseudo-Hurler.” Other indications of the disease are the onset of impaired awareness and reduced responsivity in the first days or weeks of life; lack of *psychomotor development* after 3 to 6 months; hypotonia, and later hypertonia with lively tendon reflexes and Babinski signs. Seizures are frequent. The head size is variable (microcephaly more often than macrocephaly). *Loss of vision, coarse nystagmus and strabismus, macular cherry-red spots* (in half the cases), flexion pseudocontractures of elbows and knees, kyphoscoliosis, and enlarged liver and sometimes enlarged spleen are the other important clinical findings. Radiographic abnormalities include subperiosteal bone formation, midshaft widening and demineralization of long bones, and hypoplasia and beaking of the thoracolumbar vertebrae. Vacuoles are seen in 10 to 80 percent of blood lymphocytes and foam cells in the urinary sediment.

A *partial or complete deficiency of b-galactosidase* and accumulation of G_{M1} ganglioside in the viscera and in neurons and glial cells throughout the CNS are the specific biochemical abnormalities. In addition, the epithelial cells of renal glomeruli, histiocytes of the spleen, and liver cells contain a modified keratan sulfate and a galactose-containing oligosaccharide. The changes in the bone are also like those in the Hurler form of mucopolysaccharidosis. The disease should be suspected in an infant who has the facial features of mucopolysaccharidosis and severe early-onset neurologic abnormalities.

A remarkably benign variant, also inherited as an autosomal recessive trait, begins later in childhood but may advance so slowly as to allow attainment of adult life. Dystonia, myoclonus, seizures, visual impairment, and macular red spots were features of the two cases described by [Goldman and coworkers](#).

Globoid Cell Leukodystrophy (Krabbe Disease, Galactocerebrosidase Deficiency)

This is an autosomal recessive disease without ethnic predilection, first described by Krabbe, a Danish neurologist, in 1916. The onset is usually before the sixth month and often before the third month (10 percent after 1 year). Early manifestations are *generalized rigidity*, loss of head control, diminished alertness, frequent vomiting, irritability and bouts of inexplicable crying, and spasms induced by stimulation. With increasing muscular tone, *opisthotonic* recurvation of neck and trunk develop. Later signs are adduction and extension of the legs, flexion of the arms, clenching of the fists, hyperactive tendon reflexes, and Babinski signs. Later still the tendon reflexes are depressed or lost but Babinski signs remain, an indication that *neuropathy* is added to corticospinal damage. This finding, shared with some of the other leukodystrophies, is of diagnostic value. Blindness and optic atrophy supervene. Convulsions occur but are rare and difficult to distinguish from tonic spasms. Myoclonus in response to auditory stimuli is present in some cases. The head size is normal or, rarely, slightly increased. In the last stage of the disease, which may occur from one to several months after the onset, the child is blind and usually deaf, opisthotonic, irritable, and cachectic. Most patients die by the end of the first year and survival beyond 2 years is unusual, although a considerable number of cases of later onset have been reported (see below).

The EEG shows nonspecific slowing without spikes, and the CSF protein is usually elevated (70 to 450 mg/dL). CT scanning and MRI reveal symmetrical nonenhancing areas of increased density in the internal capsules and basal ganglia. As the disease advances, more of the cerebral white matter and brainstem become involved ([Fig. 37-2](#)). Clinical signs of neuropathy may be difficult to detect except for a decrease or loss of tendon reflexes, but *electromyographic (EMG) evidence of denervation and slowed motor and sensory nerve conduction velocities*, reflecting a demyelinating type of polyneuropathy, are frequent findings.

Figure 37-2 *Krabbe disease. T2-weighted MRI in the axial plane demonstrating an abnormal high signal in the periventricular white matter. Arcuate fibers are spared. The patient was a 14-month-old boy with severe generalized rigidity. Diagnosis was proved postmortem (4 months after the MRI). (From Lee SH, Rao K, Zimmerman RA: Cranial MRI and CT, 3rd ed. New York, McGraw-Hill, 1992, by permission.)*

The deficient enzyme in Krabbe disease is *galactocerebrosidase* (also called galactosylceramide b-galactosidase, or GALC). It results in the accumulation of galactocerebroside, particularly in the cerebral white matter. The gene mutation is located on chromosome 14q. Gross examination of the brain discloses a marked reduction in the cerebral white matter, which feels firm and rubbery. Microscopically, there are widespread myelin degeneration and gliosis in the cerebrum, brainstem, spinal cord, and nerves. The characteristic globoid cells are large histiocytes containing the accumulated metabolite. Schwann cells have tubular or crystalloid inclusions under electron microscopy.

About a dozen variants of globoid cell leukodystrophy have been reported, many of them allowing survival for years. In these, neurologic regression begins in the 2- to 6-year period. Visual failure with optic atrophy and normal electroretinogram is an early finding. Later there is ataxia as well as spastic weakness of the legs, mental regression, and finally decerebration. In three patients observed by [R. D. Adams](#), a progressive quadriparesis with mild pseudobulbar signs, slowly progressive impairment of memory and other mental functions, dystonic posturing of the arms, and preserved sphincteric control constituted the clinical picture. The patients were alive at ages 9, 12, and 16 years. We have observed another rare variant, beginning in adult years, with spastic quadriparesis (asymmetrical) and optic atrophy. Mentation was essentially normal and, on CT scanning and MRI, the cerebral lesion was restricted. Unlike typical Krabbe disease, these CNS abnormalities are unaccompanied by any change in the spinal fluid. The nerve conduction velocities in the late-onset form may be either normal or abnormal.

Kolodny and colleagues have reported 15 cases of even later onset (ages 4 to 73 years); pes cavus, optic pallor, progressive spastic quadriparesis, a demyelinating sensorimotor neuropathy, and symmetrical parieto-occipital white matter changes (on imaging studies) were the main features. Galactocerebrosidase levels were not as much reduced as in the infantile form; possibly these late-onset variants represent a structural mutation of the enzyme (see [Farrell and Swedberg](#)).

In this disease, as well as others described in this chapter, it has become clear that different mutations involving the same enzyme or metabolic pathway can produce strikingly different phenotypes and that there is a wide range in the age of onset in what had been considered, until relatively recently, a disease confined to infancy and early childhood.

Lipogranulomatosis (Farber Disease, Ceramidase Deficiency)

This is a very rare disorder that is probably genetic, affecting both sexes and without a particular racial predilection. The onset is in the first weeks of life, with a hoarse cry due to fixation of laryngeal cartilage, respiratory distress, and sensitivity of the joints, followed by characteristic *periarticular and subcutaneous swellings* and *progressive arthropathy* leading finally to ankylosis. Usually there is severe psychomotor retardation, but a few patients have appeared neurologically normal. Inanition and recurrent infections lead to death in the first 2 years. The diagnostic abnormality is a *deficiency of ceramidase*, leading to accumulation of ceramide. There is widespread lipid storage in neurons, granulomas of the skin, and accumulation of periodic acid–Schiff (PAS)-positive macrophages in periarticular and visceral tissues.

Sudanophilic Leukodystrophies and Pelizaeus-Merzbacher Disease

These are a heterogeneous group of disorders that have in common a defective myelination of the cerebrum, brainstem, cerebellum, spinal cord, and peripheral nerves. Morphologic peculiarities and genetic features separate a certain group called *Pelizaeus-Merzbacher disease*; other types have been artificially delineated; as a result, a relatively meaningless terminology has been introduced.

Pelizaeus-Merzbacher Disease This is predominantly an X-linked disease of infancy, childhood, and adolescence and includes other closely related pathologic entities with different modes of inheritance. The gene is the same as the one that encodes proteolipid protein, one of the two myelin basic proteins; Koeppen and associates have offered evidence of a defective synthesis of this protein.

The onset of symptoms is most often in the first months of life; other cases begin later in childhood. The first signs are *abnormal movements of the eyes* (rapid, irregular, often asymmetrical pendular nystagmus), jerk nystagmus on extremes of lateral movements, upbeat nystagmus on upward gaze, and hypometric saccades ([Trobe et al](#)). There is spastic weakness of the limbs, ataxia, optic atrophy, intention tremor, choreiform or athetotic movements of the arms, and slow psychomotor development with delay in sitting, standing, and walking. Seizures occur occasionally. In later-developing cases, pendular nystagmus, choreoathetosis, corticospinal signs, dysarthria, cerebellar ataxia, and mental deterioration are the major manifestations. CT scanning and MRI confirm the white matter involvement. Patients may survive to the second and third decades. One group of cases resembles the Cockayne syndrome (page 1018), with photosensitivity of skin, dwarfism, cerebellar ataxia, corticospinal signs, cataracts, retinitis pigmentosa, and deafness. Pathologically, islands of preserved myelin impart a tigroid pattern of degenerated and intact myelin in the cerebrum. Seitelberger has obtained pathologic verification of this lesion in cases beginning as late as adult years. *This disease and Cockayne syndrome are the only leukodystrophies in which nystagmus has been an invariable finding.*

Unclassifiable Sporadic and Familial Sudanophilic Leukodystrophies There are two types of disorder, one with early and the other with late onset. In the former, onset is before 3 months with survival of less than 2 years; in the latter type, onset is from 3 to 7 years and the course is chronic. *Psychomotor regression; spastic paralysis; incoordination; blindness* and optic atrophy; seizures (rare); *severe microcephaly*; and absence of skeletal, visceral, and hematologic evidence of the metabolic abnormality are the main features. No characteristic laboratory abnormalities are known. Diffuse degeneration of medullated fibers with phagocytosis of *sudanophilic degeneration products of myelin* (visible by MRI) and gliosis are the major changes. In two cases followed by [R. D. Adams](#), a brother and sister living to adolescence, the destroyed white matter was widely cavitated.

Spongy Degeneration of Infancy ([Canavan-Van Bogaert-Bertrand Disease](#))

This is an autosomal recessive disease first described by Canavan as Schilder disease in 1931 but later categorized as a spongy degeneration of the brain by [Van Bogaert and Bertrand in 1949](#). Of 48 affected families reported by [Banker and Victor](#), 28 were Jewish. Onset is early, often recognizable in the first 3 months of life. There is either a lack of development or rapid *regression of psychomotor function, loss of sight and optic atrophy*, lethargy, difficulty in sucking, irritability, reduced motor activity, hypotonia followed by spasticity of the limbs with corticospinal signs, and an *enlarged head* (macrocephaly). There are no visceral or skeletal abnormalities. Seizures occur in some cases. An interesting but unexplored aspect of the disease is the occurrence of blond hair and light complexion in affected members, in contrast to the darker hair and complexion of their normal siblings ([Banker and Victor](#)).

The CSF is usually normal, but the protein is slightly elevated in some cases. The disease is characterized by an increased urinary excretion of *N*-acetyl-L-aspartic acid (NAA), which may be used as a biochemical marker. It reflects the basic enzyme abnormality, a deficiency of aspartoacylase ([Matalon et al](#)). On CT scans there is *attenuation of cerebral and cerebellar white matter in an enlarged brain with relatively normal ventricles*. The MRI appearance ([Fig. 37-3](#)) is that of diffuse high signal intensity on T2-weighted images. A leukodystrophy with behavioral regression, an enlarging head, a characteristic MRI abnormality, and a marked elevation of urinary NAA should leave little doubt about the diagnosis.

Figure 37-3 Spongy degeneration of infancy ([Canavan–van Bogaert disease](#)). T2-weighted axial MR image from an infant with a positive urine assay for N-acetyl aspartic acid. The abnormal white matter appears hyperintense and extends to the cortex without sparing of the arcuate fiber. (From Lee SH, Rao K, Zimmerman RA: *Cranial MRI and CT*, 3rd ed. New York, McGraw-Hill, 1992, by permission.)

The characteristic pathologic changes are an increase in brain volume (and weight), spongy degeneration in the deep layers of the cerebral cortex and subcortical white matter, widespread loss of myelin involving the convolutional more than the central white matter, loss of Purkinje cells, and hyperplasia of Alzheimer type II astrocytes throughout the cerebral cortex and basal ganglia. Adachi and coworkers have demonstrated an abnormal accumulation of fluid in astrocytes and between split myelin lamellae; they have suggested that the loss of myelin is secondary to these changes.

The disease must be distinguished clinically from G_{M2} gangliosidosis, Alexander disease, Krabbe disease, and nonprogressive megaloccephaly and pathologically from a variety of disorders characterized by vacuolation of nervous tissue.

Alexander Disease

The classification of this rare disease is uncertain. A familial incidence has not been reported, and no metabolic fault has been defined. It shares certain features with the leukodystrophies and gray matter diseases (poliodystrophies), both clinically and pathologically. The onset is in infancy with a *failure to thrive, psychomotor retardation, and seizures*. An early and progressive macrocephaly has been a consistent feature. Pathologically, there are severe destructive changes in the cerebral white matter, most intense in the frontal lobes. Distinctive eosinophilic hyaline bodies, most prominent just below the pia and around blood vessels, are seen throughout the cerebral cortex, brainstem, and spinal cord. These have been identified as *Rosenthal fibers* and probably represent glial degradation products.

Alpers Disease This is a progressive disease of the cerebral gray matter, known also as *progressive cerebral poliodystrophy or diffuse cerebral degeneration in infancy*. A familial form (probably autosomal recessive) and some sporadic cases are known. In both groups there is a certain uniformity of clinical features—loss of smile and disinterest in the surroundings, sweating attacks, *seizures and diffuse myoclonic jerks* from early infancy, followed by incoordination of movements; progressive spasticity of limb, trunk, and cranial muscles; blindness and optic atrophy; growth retardation and *increasing microcephaly*; and finally, virtual decortication. In some instances, the late onset of jaundice and fatty degeneration or cirrhosis of the liver have been described ([Alpers-Huttenlocher syndrome](#)); the hepatic changes are distinctive and probably not related to the use of anticonvulsant drugs ([Harding et al](#)). By the age of 4 years these patients are hypotonic, anemic, and thrombopenic; they also show hair changes (trichorrhexis).

The nature of this combined hepatic-cerebral degeneration remains unexplained, but some instances have been connected to the mitochondrial disorders, as noted below. EEG abnormalities, progressive atrophy (particularly occipital) on the CT scan, loss of visual evoked potentials, and abnormal liver function tests are diagnostically useful. Neuropathologic examination shows marked atrophy of the cerebral convolutions and cerebellar cortex, with loss of nerve cells and fibrous gliosis (“walnut brain”). The cerebral white matter and basal ganglia are relatively preserved. In some cases, the spongiform vacuolization of the gray matter of the brain resembles that seen in Creutzfeldt-Jakob disease. Hypoglycemic, hypoxic, and hypotensive encephalopathies must always be considered in the diagnosis but can usually be eliminated by knowledge of the clinical circumstances at the onset of the illness.

A number of biochemical abnormalities have been identified in patients with Alpers disease, including pyruvate dehydrogenase deficiency, decreased pyruvate utilization, dysfunction of the citric acid cycle, and decreased cytochromes *a* and *aa*₃. The biochemical and pathologic changes suggest a relationship to Leigh encephalomyelopathy and a mitochondrial transmission. Many authoritative texts classify it with the mitochondrial diseases, but the nosologic place of the disease is in our opinion still uncertain ([Shaffner and Wallace](#); see further on).

Congenital Lactic Acidosis

This is an uncommon disease of the neonatal period or early infancy, of many biochemical etiologies. The symptoms have consisted of *psychomotor regression and episodic hyperventilation, hypotonia, and convulsions*, with intervening periods of normalcy. *Choreoathetosis* has been observed in a few cases. Death often occurs before the third year. The important laboratory findings are *acidosis with an anion gap and high serum lactate levels* and hyperalaninemia. Defects can be found in the pyruvate dehydrogenase complex of enzymes and the electron transport chain complexes, which function in the oxidative decarboxylation of pyruvate to acetyl CoA—relating the disease to defects in the mitochondrial respiratory chain enzymes. Indeed, lactic acidosis is a feature of several of the mitochondriopathies discussed later in the chapter. Cases that have been examined postmortem have shown necrosis and cavitation of the globus pallidus and cerebral white matter. Possibly this is a variant of Leigh disease (page 1042). It must be distinguished from the several diseases of infancy that are complicated secondarily by lactic acidosis, especially the organic acidopathies. Cases of benign transient infantile lactic acidosis have been reported, but their etiology is unclear.

Cerebrohepatorenal (Zellweger) Disease (Peroxisomal Disorder)

This disease, estimated to occur once in every 100,000 births, is inherited as an autosomal recessive trait. It has its onset in the neonatal period or early infancy and as a rule leads to death within a few months. Motor inactivity and hypotonia, *dysmorphic alterations of the skull and face* (high forehead, shallow orbits, hypertelorism, high arched palate, abnormal helices of ears, retrognathia), poor visual fixation, multifocal seizures, swallowing difficulties, fixed flexion posture of the limbs, cataracts, abnormal retinal pigmentation, optic atrophy, cloudy corneas, hepatomegaly, and hepatic dysfunction are the usual manifestations. *Stippled, irregular calcifications of the patellae and greater trochanters are highly characteristic*. Pathologically, there is dysgenesis of the cerebral cortex and degeneration of white matter as well as a number of visceral abnormalities—cortical renal cysts, hepatic fibrosis, intrahepatic biliary dysgenesis, agenesis of the thymus, and iron storage in the reticuloendothelial system.

As to the biochemical abnormality, A. B. Moser and coworkers have demonstrated a fivefold increase of very long chain fatty acids, particularly hexacosanoic acid, in the plasma and cultured skin fibroblasts from 35 patients with Zellweger disease. A similar abnormality was found in cultured amniocytes of women at risk of bearing a child with Zellweger disease, thus permitting prenatal diagnosis. The findings of Moser and colleagues are in keeping with current notions about the basic abnormality in Zellweger syndrome—namely, that it is due to a lack of liver peroxisomes (oxidase-containing, membrane-bound cytoplasmic organelles), in which the very long chain fatty acids are normally oxidized ([Goldfischer et al](#)).

Currently, a spectrum of at least 10 disorders of peroxisomal function is recognized, all of them characterized by deficiencies in the peroxisomal enzyme of fatty acid oxidation—a veritable peroxisomal assembly. The Zellweger cerebrohepatorenal syndrome is the prototype. Each variant can be identified by its characteristic profile of elevated long and very long chain fatty acids and the specific diagnosis confirmed by enzymology of cultured fibroblasts or amniocytes.

The Oculocerebrorenal (Lowe) Syndrome

Here the mode of inheritance is probably X-linked recessive, although sporadic cases have been reported in girls. The clinical abnormalities comprise *bilateral cataracts* (which may be present at birth), glaucoma, large eyes with megalocornea and buphthalmos, corneal opacities and blindness, pendular nystagmus, hypotonia and absent or depressed tendon reflexes, corticospinal signs without paralysis, slow movements of the hands, high-pitched cry, occasional seizures, and

Neurologic signs that are more or less specific for certain metabolic diseases are as follows:

1. Acousticomotor obligatory startle: Tay-Sachs disease
2. Abolished tendon reflexes with definite Babinski signs: globoid cell (Krabbe) leukodystrophy, occasionally Leigh disease, and (beyond infancy) metachromatic leukodystrophy
3. Peculiar eye movements, pendular nystagmus, and head rolling: Pelizaeus-Merzbacher disease, Leigh disease; later, hyperbilirubinemia and Lesch-Nyhan hyperuricemia (see further on)
4. Marked rigidity, opisthotonos, and tonic spasms: Krabbe, Alpers disease, or infantile Gaucher disease (classic triad: trismus, strabismus, opisthotonos.)
5. Intractable seizures and generalized or multifocal myoclonus: Alpers disease
6. Intermittent hyperventilation: Leigh disease and congenital lactic acidosis (also nonprogressive familial agenesis of vermis)
7. Strabismus, hypotonia, seizures, lipodystrophy: carbohydrate deficient glycoprotein syndrome

Ocular abnormalities of specific diagnostic value:

1. Rapid pendular nystagmus: Pelizaeus-Merzbacher disease, rarely Krabbe leukodystrophy
2. Macular cherry-red spots: Tay-Sachs disease and Sandhoff variant, some cases of infantile Niemann-Pick disease, and rarely lipofuscinosis
3. Corneal opacification: Lowe disease, infantile G_{M1} gangliosidosis; later, the mucopolysaccharidoses
4. Cataracts: galactosemia, Lowe disease, Zellweger disease (also congenital rubella)

Other medical findings of specific diagnostic value:

1. Dysmorphic facies: generalized G_{M1} gangliosidosis, Lowe and Zellweger syndromes, and some early cases of mucopolysaccharidosis and mucopolipidosis
2. Enlarged liver and spleen: infantile Gaucher disease and Niemann-Pick disease; one type of hyperammonemia; Sandhoff disease; later, the mucopolysaccharidoses and mucopolipidoses
3. Enlarging head without hydrocephalus (macrocephaly): Canavan spongy degeneration of infancy, some cases of Tay-Sachs disease, Alexander disease
4. Beaking of vertebral bodies in radiographs: G_{M1} gangliosidosis (and, at a more advanced age, the mucopolysaccharidoses, fucosidosis, mannosidosis, and the mucopolipidoses)
5. Multiple arthropathies and raucous dysphonia: Farber disease
6. Storage granules and vacuolated lymphocytes: Niemann-Pick disease, generalized G_{M1} gangliosidosis
7. Abnormal histiocytes in marrow smears: Gaucher cells, foamy histiocytes in Niemann-Pick disease, generalized G_{M1} gangliosidosis and closely related diseases, Farber disease
8. Colorless, friable hair: Menkes disease

INHERITED METABOLIC DISEASES OF EARLY CHILDHOOD

Included here are the diseases that become manifest between the ages of 1 and 4 years. Diagnosis is less difficult than in the neonate and young infant. A morbid process in the nervous system is reliably ascertained by the obvious progression of a neurologic disorder, such as a loss of ability to walk and to speak, which usually parallels a regression in other high-level (quasi-intellectual) functions. Embryologic anomalies, prenatal diseases, and birth injuries can be excluded with relative certainty if psychomotor development was normal in the first year or two. Diseases characterized by seizures and myoclonus may prove more difficult to interpret, for the seizures may occur at any age from a variety of distant or immediate neurologic causes and, if frequent, may cause a significant impairment of psychomotor function. The effects of anticonvulsant medications may add to the impairment of cortical function. Unfortunately, most of the slowly advancing metabolic diseases of the second year may be so subtle in their effects that for a time the physician cannot be sure whether a regression of intellectual functions is taking place or mental retardation is becoming apparent for the first time. To distinguish the two is more difficult if the parents have been unobservant. Repeated examinations and testing will usually settle the matter. Suspicion of a progressive encephalopathy is heightened by the presence of certain ocular, visceral, and skeletal abnormalities, as described below.

Once a neurologic syndrome is clearly established, there is an advantage in determining whether its main characteristics reflect a disorder of the cerebral white matter (oligodendrocytes and myelin) or of gray matter (neurons). Indicative of predominantly white matter affection (*leukodystrophy* or leukoencephalopathy) are early onset of spastic paralysis of the limbs, with or without ataxia, and visual impairment with optic atrophy but normal retinæ. Seizures and intellectual deterioration are late events. MRI usually confirms the involvement of white matter. Indicative of gray matter disease (poliodystrophy or polioencephalopathy) are the early onset of seizures, myoclonus, blindness with retinal changes, and mental regression. Chorea and ataxia, spastic paralysis, and signs of sensorimotor tract involvement occur later. On MRI, only a generalized atrophy and ventricular enlargement may be seen.

Neuronal storage diseases, such as those described in the previous section, as well as neuroaxonal dystrophy and the lipofuscinoses, conform to the pattern of gray matter diseases ([Table 37-4](#)). Metachromatic, globoid-body, sudanophilic leukodystrophy and spongy degeneration of infancy exemplify white matter diseases ([Table 37-5](#)). Although this mode of categorization is helpful, there is some degree of overlap; for example, Tay-Sachs disease, a poliodystrophy, also causes white matter changes, and metachromatic leukodystrophy may be accompanied by some degree of neuronal storage.

The following are inherited metabolic diseases that occur most frequently in late infancy and early childhood:

1. Many of the milder disorders of amino acid metabolism
2. Metachromatic leukodystrophy
3. Late infantile G_{M1} gangliosidosis
4. Late infantile Gaucher disease and Niemann-Pick disease
5. Neuroaxonal dystrophy
6. The mucopolysaccharidoses
7. The mucopolipidoses
8. Fucosidosis
9. The mannosidoses
10. Aspartylglycosaminuria
11. Ceroid lipofuscinosis (Jansky-Bielschowsky)
12. Cockayne syndrome

The Aminoacidopathies (Aminoacidurias)

In a group of 48 inherited aminoacidopathies, tabulated by [Rosenberg and Scriver](#), at least one-half were associated with recognizable neurologic abnormalities. Twenty other aminoacidopathies result in a defect in the renal transport of amino acids, and some of the latter may secondarily damage the nervous system. Usually, when the nervous system is involved, the only clinical manifestation is simply a lag in psychomotor development which, if mild, does not become evident until the second and third years or later. Like other inherited metabolic disorders, the aminoacidurias do not impair growth, development, and maturation in utero or interfere with parturition. No physical sign betrays their presence in the early months of life. The only possible means of detection is by screening all newborns. The relative frequency of these diseases is indicated in [Table 37-1](#), and the practical tests for their identification are summarized in [Table 37-2](#).

Three aminoacidopathies of the late infantile and early childhood period—phenylketonuria (PKU), tyrosinemia, and Hartnup disease—are described here because of their clinical importance and because they exemplify different types of biochemical defect. Reference is also made to certain other aminoacidurias, described in the first part of this chapter, which, like Hartnup disease, are associated with intermittent ataxia. Only passing comments are made about the other aminoacidurias, which are exceedingly rare or have only an uncertain effect upon the nervous system. A detailed and current account of these disorders can be found in the monograph of Scriver and coworkers.

The Phenylketonurias (PKU, Phenylalanine Hydroxylase Deficiency) Apart from being the most frequent of the aminoacidurias, this entity has a special historical

significance. Since its discovery by [Følling in 1934](#), it has remained the classic example of an aminoaciduria, illustrating three principles of medical genetics: first, it is inherited as an autosomal recessive trait; second, PKU exemplifies Garrod's cardinal principle of gene action, in which genetic factors specify chemical reactions as well as biochemical individuality; third, PKU is a disease, and hyperphenylalaninemia is a phenotype only when the allele is expressed in an environment that contains an abundance of L-phenylalanine. Thus, as predicted by Galton, the ultimate phenotype is a product of "nature and nurture" ([Scriver and Clow](#)).

One must refer to the phenylketonurias in the plural, for there are (1) the usual type and several mild and severe variants thereof, in all of which mental retardation is invariable if the disease is not treated early in life, and (2) other types, presumably allelic mutations, in which there is hyperphenylalaninemia without PKU and without effect on the nervous system. Also there are a small number of patients (3 percent in our series) in whom a lowering of the hyperphenylalaninemia does not prevent the progression of the neurologic lesion.

At birth, the typical PKU infant is believed to have a normal nervous system. The disease appears later, only after long exposure of the nervous system to PA, because the homozygous infant lacks the means of protecting the nervous system. However, if the mother is homozygous with high PA levels in the blood, the CNS is damaged in utero and the heterozygous infant is mentally defective from birth.

In the classic form of PKU, the *impairment of psychomotor development* can usually be recognized in the latter part of the first year, when expected performances lag. By 5 to 6 years in an untreated child, when the IQ can be estimated, it is usually less than 20, occasionally 20 to 50, and exceptionally above 50. *Hyperactivity*, aggressivity, self-injurious behavior, including severe injury to the eyes, clumsy gait, fine tremor of the hands, poor coordination, odd posturings, *repetitious digital mannerisms* and other so-called rhythmicias, and slight corticospinal tract signs stand out as the main clinical manifestations. Athetosis, dystonia, and frank cerebellar ataxia have been described but must be exceedingly rare. Also, seizures are said to occur in 25 percent of severely retarded patients, taking the form at first of flexor spasms and later of absence and grand mal attacks. However, of more than 30 of our PKU patients at the Fernald School, none had seizures or extrapyramidal signs. The majority are blue-eyed and fair in skin and hair color, and their skin is rough and dry and subject to eczema. A musty body odor (due to phenylacetic acid excretion) can often be detected. Two-thirds are slightly microcephalic. The fundi are normal, and there is no visceral enlargement or skeletal abnormality.

The finding of *high levels of serum phenylalanine* (above 15 mg/dL) and of *phenylpyruvic acid in the blood, CSF, and urine* are diagnostic of PKU. The level is normal at birth and rises only after the first few days. Screening by the Guthrie (ferric chloride) test then identifies the patient at risk: the addition of 3 to 5 drops of 10% ferric chloride to 1 mL of urine yields an emerald-green color that reaches a peak intensity in 3 to 4 min and fades in 20 to 40 min. In contrast, the green-brown color in the urine of patients with histidinemia is permanent. In maple syrup urine disease, the ferric chloride test gives a navy-blue color; propionic and methylmalonic acidemia and ketones or salicylates in the urine yield a purple color.

The fundamental biochemical abnormality is a deficiency of the hepatic enzyme PA hydroxylase; the failure of conversion of PA to tyrosine results in the excretion of phenylpyruvic acid by affected individuals. The precise step that is faulty in the complex phenylalanine hydroxylating reaction is still unknown. The mutant gene has been localized on chromosome 12. Pathologic examination shows poor staining of myelin in the cerebral hemispheres. The usually pigmented nuclei (substantia nigra, locus ceruleus, dorsal vagal motor) fail to acquire dark coloration because of a block in the production of melanin. Reduction in size of cortical neurons and their dendritic arborizations is said to be demonstrable in some cases.

If instituted in infancy, diets low but not totally lacking in PA can improve intellectual development (blood level should be maintained at 5 to 10 mg/dL). Once the neurologic picture unfolds, diet has little or no effect on the mental status but may improve behavior. Prolonged dietary treatment has many untoward effects and should be supervised by physicians experienced in its use; if too restricted, it may retard growth. This is particularly important, since it has been shown that intellectual impairment is greatest among children who were the earliest to abandon their diets, permitting the PA concentration to rise above 15 mg/dL, and least in children who maintained dietary control the longest ([Holtzman et al](#)). Continued dietary treatment is necessary. In children with hyperphenylalaninemia but without PKU, dietary treatment is not indicated. With the widespread screening for PKU and the initiation of dietary control during early postnatal life, this metabolic brain disease has virtually disappeared in our states. Treated women who reach childbearing age should be particularly careful about dietary restriction, since high levels of phenylalanine are harmful to the normal fetus.

The late forms of maple syrup urine disease, histidinemia, and hydroxyprolinemia evolve in much the same fashion as PKU and raise similar problems in diagnosis and therapy.

A small number of infants have a variant of PKU in which a restricted PA diet does not prevent neurologic involvement. In some such infants, a dystonic extrapyramidal rigidity ("stiff-baby syndrome") has been present as early as the neonatal period, and, according to Allen and coworkers, it responds to biopterin. Such infants have normal levels of PA hydroxylase in the liver. The defect is a failure to synthesize the active cofactor tetrahydrobiopterin, because of either an insufficiency of dihydropteridine reductase or an inability to synthesize biopterin (see page 989). The urinary metabolites of catecholamines and serotonin are reduced and are not responsive to low-PA diets. There is some evidence that the underlying neurotransmitter fault can be corrected by L-dopa and 5-hydroxytryptophan ([Scriver and Clow](#)).

Hereditary Tyrosinemia (Richner-Hanhart Disease) This is a rare, predominantly dermatologic aminoacidopathy, but in approximately one-half of the infants there is a mild to moderate degree of mental retardation. Also, there may be self-mutilation and incoordination of limb movements. Language defects are prominent. Toward the end of the first or second year of life, lacrimation, photophobia, and redness of the eyes (due to corneal erosions) appear. Neovascularization of the corneas and opacification follow. Palmar and plantar keratosis with hyperhidrosis and pain are frequently present as a result of an inflammatory reaction to deposits of crystalline tyrosine (also the cause of the corneal changes). Elevated tyrosine in the blood (>0.18 mM) and urine are diagnostic. The disease is due to a defect on chromosome 15 that codes for the enzyme fumarylacetoacetate hydrolase, a deficiency of which results in the accumulation of tyrosine and its metabolites.

A low-tyrosine and low-PA diet, optimized to allow growth and development, has resulted in rapid amelioration of symptoms but must be started early. Retinoids given orally improve the skin lesions. Neonatal tyrosinemia can cause liver failure and early death.

Hartnup Disease This disease, named after the family in which it was first observed, is probably transmitted as an autosomal recessive trait. Women carrying this trait deliver babies who are normal at birth. The onset of symptoms is in late infancy or early childhood. The clinical features consist of an *intermittent red, scaly rash over the face, neck, hands, and legs*, resembling that of pellagra; growth failure and developmental delay; episodic personality disorder in the form of *emotional lability*, uncontrolled temper, and confusional-hallucinatory psychosis; *episodic cerebellar ataxia* (unsteady gait, intention tremor, and dysarthria); and occasionally spasticity, vertigo, nystagmus, ptosis, and diplopia. Attacks of disease are triggered by exposure to sunlight, emotional stress, and sulfonamide drugs and last for about 2 weeks, followed by variable periods of relative normalcy. The frequency of attacks diminishes with maturation, but some children are left with a mild persistent mental retardation.

The metabolic faults are due to a *transport error of neutral amino acids across renal tubules, with excretion of greatly increased amounts of these amino acids in the urine and feces*. In particular, there is the excretion of large amounts of indicans, mainly indoxyl sulfate, particularly after oral L-tryptophan loading; and an abnormally high excretion of nonhydroxylated indole metabolites. Loss of tryptophan in the urine reduces its availability for the synthesis of niacin and accounts for the pellagrous skin changes. The pathologic basis of the disease is undetermined. Differential diagnosis includes a large number of intermittent and progressive cerebellar ataxias of childhood, described below.

Treatment consists of avoiding exposure to sunlight and to sulfonamide drugs. Because of the similarities between pellagra and Hartnup disease, the usual practice is to give nicotinamide in doses of 50 to 300 mg daily. The skin lesions disappear and there are reports of subsidence of ataxia and psychotic behavior. However, the results of treatment are inconsistent. Possibly a better response is obtained by the administration of L-tryptophan ethyl ester in doses of 20 mg/kg tid.

Other Metabolic Diseases with Intermittent or Persistent Ataxia, Seizures, and Mental Retardation In addition to Hartnup disease, a number of other metabolic diseases give rise to episodic ataxias during early childhood. These are (1) mild forms of maple syrup urine disease and the congenital hyperammonemias (type II hyperammonemia, citrullinemia, argininosuccinic aciduria, hyperornithinemia), described in an earlier part of the chapter; (2) necrotizing encephalomyelopathy (Leigh), described further on; (3) hyperalaninemia and hyperpyruvic acidemia ([Lonsdale et al](#), [Blass et al](#)); and (4) autosomal dominant, acetazolamide-responsive ataxia that may have its onset in childhood but usually appears later (page 1022).

In all these conditions the ataxia, which is of cerebellar type, is highly variable from time to time and may follow a burst of seizures (as in argininosuccinic aciduria). The seizures are treated with anticonvulsant drugs, which may at first be held responsible for the ataxia. In time, however, it becomes apparent that the ataxia lasts a week or two and bears no relationship to the medicine. Indeed, seizures and ataxia are both due to the common biochemical abnormality. Between attacks, in all the

intermittent ataxias, the patient's movements are relatively normal, but most of the affected children are slow in learning and remain backward mentally to a varying degree.

The Problem of Progressive Cerebellar Ataxia of Early Childhood

The differentiation of the childhood ataxias is difficult. The problem is twofold—first, to be certain that ataxia exists, and, second, to differentiate cerebellar ataxia from the sensory ataxia of peripheral nerve disease and from generalized tremor and polymyoclonus. Since cerebellar ataxia is more a disorder of voluntary than of postural movements, its presence usually cannot be determined with certainty until intentional (projected) movements become part of the child's repertoire of motor activity. As indicated in [Chap. 28](#), the earliest signs become manifest in the arms when the infant reaches for an object and brings it to his mouth or transfers it from hand to hand. A jerky, wavering, tremulous movement then appears; in sitting, a titubation of the head and a tremor of the trunk may be apparent. Once walking begins, apart from the usual clumsiness of the toddler, there is a similar inco-ordination of movement. Sensory ataxia is always difficult to distinguish but is rare at this age and usually accompanied by weakness and absence of tendon reflexes. By the fourth or fifth year, when more detailed sensory testing becomes possible, the presence or absence of a proprioceptive disturbance can be demonstrated.

The group of persistent and progressive cerebellar ataxias is heterogeneous and of varied etiology; some of them merge with Friedreich ataxia, Levy-Roussy neuropathy, and other adolescent-adult hereditary ataxias. These disorders are discussed in the chapter on degenerative diseases, since, apart from their hereditary nature, neither their cause nor their pathogenesis is known. There are many other childhood ataxias that probably belong in the category of degenerative disease, some in which cerebellar ataxia is the most prominent abnormality and some in which other neurologic abnormalities are more prominent. To describe each in detail would be impractical in a book on the principles of neurology, for which reason they are only tabulated here.

1. The disequilibrium and dyssynergia syndrome of Hagberg and Janner: early-life onset of relatively pure cerebellar ataxia, with psychomotor retardation.
2. Cerebellar ataxia with diplegia, hypotonia, and mental retardation (also called *atonic diplegia* of Foerster); this is either a fetal disease or birth injury and the neuropathology is uncertain.
3. Agenesis of the cerebellum: early cerebellar ataxia (with or without mental retardation) and episodic hyperventilation (Norman's family with granule-cell degeneration falls into this category).
4. Cerebellar ataxia with cataracts and oligophrenia: onset from childhood (mainly) to as late as adult years ([Marinesco-Sjögren](#) disease).
5. Familial cerebellar ataxia and retinal degeneration.
6. Familial cerebellar ataxia with cataracts and ophthalmoplegia or with cataracts and mental as well as physical retardation.
7. Familial cerebellar ataxia with mydriasis.
8. Familial cerebellar ataxia with deafness and blindness and a similar combination, called retinocochleodentate degeneration, referring to loss of neurons in these three structures.
9. Familial cerebellar ataxia with choreoathetosis, corticospinal tract signs, and mental and motor retardation.

In none of the syndromes mentioned above has a biochemical abnormality been established, so their metabolic nature is a matter of speculation. However, disorders of the electron transport chain can, on occasion, present as the Marinesco-Sjögren phenotype, mentioned above.

The persistent cerebellar ataxias of childhood in which a metabolic fault or gene defect has been demonstrated are (1) Refsum disease, (2) abetalipoproteinemia ([Bassen-Kornzweig](#) syndrome), (3) ataxia-telangiectasia, (4) galactosemia, and (5) possibly Friedreich ataxia. Refsum disease is discussed with the hereditary polyneuropathies (page 1421). The Bassen-Kornzweig syndrome more often has its onset in late than in early childhood and is more appropriately described in the following section of this chapter. Ataxia-telangiectasia is described below. Galactosemia has been described on page 990 and Friedreich ataxia on page 1145. Generally, it is not difficult to differentiate these diseases from the acquired postinfectious variety that occurs predominantly in children.

Ataxia-Telangiectasia This disease, sometimes referred to as the *Louis-Bar syndrome*, was first described by Sylaba and Henner in 1926, long before Louis-Bar's report in 1941. Like xeroderma pigmentosum and the Cockayne syndrome, ataxia-telangiectasia has been attributed to defective repair of DNA. The inheritance pattern is autosomal recessive. The disorder first presents as an ataxic-dyskinetic syndrome in children who appear to have been normal in the first few years of life. The onset of the disease coincides more or less with the acquisition of walking, which is awkward and unsteady. Later, by the age of 4 to 5 years, the limbs become ataxic, and choreoathetosis, grimacing, and dysarthric speech are added. The eye movements become jerky, with slow and long-latency saccades, and there is also apraxia for voluntary gaze (the patient turns the head but not the eyes on attempting to look to the side). Optokinetic nystagmus is lost. By the age of 9 to 10 years, slight intellectual decline sets in and signs of mild polyneuropathy are evident. Muscle power is reduced little if at all until late in the illness, but tendon reflexes may disappear. The characteristic telangiectatic lesions, which are mainly transversely oriented subpapillary venous plexuses, appear at 3 to 5 years of age or later and are most apparent in the outer parts of the bulbar conjunctivae ([Fig. 37-5](#)), over the ears, on exposed parts of the neck, on the bridge of the nose and cheeks in a butterfly pattern, and in the flexor creases of the forearms. Vitiligo, café-au-lait spots, loss of subcutaneous fat, and premature graying of hair are observed in some patients. Many of the patients have endocrine alterations (absence of secondary sexual development, glucose intolerance). The disease is progressive, and death usually occurs in the second decade from intercurrent bronchopulmonary infection or neoplasia—usually lymphoma, less often glioma ([Boder and Sedgwick](#)).

Figure 37-5 Ocular appearance of ataxia-telangiectasia. (From [Lyon et al](#) by permission.)

The significant abnormalities in the CNS are severe degeneration in the cerebellar cortex; loss of myelinated fibers in the posterior columns, spinocerebellar tracts, and peripheral nerves; degenerative changes in the posterior roots and cells of the sympathetic ganglia; and loss of anterior horn cells at all levels of the spinal cord. In a few cases, vascular abnormalities, like the mucocutaneous ones, have been found scattered diffusely in the white matter of the brain and spinal cord, but they are of questionable significance. Also, there may be a loss of pigmented cells in the substantia nigra and locus ceruleus, and cytoplasmic inclusions (Lewy bodies) in the cells that remain ([Agamanolis and Greenstein](#)). Intranuclear inclusions and bizarre nuclear formations have also been found in the satellite cells (amphicytes) of dorsal root ganglion neurons ([Strich](#)).

An absence or decrease in several immunoglobulins—IgA, IgE and isotypes, IgG₂, IgG₄—has been found in practically every patient. These deficiencies, shown by [McFarlin and associates](#) to be due to decreased synthesis, are associated with hypoplasia of the thymus, loss of follicles in lymph nodes, failure of delayed hypersensitivity reactions, lymphopenia, and slow formation of circulating antibodies. There are breaks in chromosome 14 and, the abnormal gene has now been identified. After radiation, there is faulty repair of DNA. Probably this immunodeficient state accounts for the striking susceptibility of these patients to recurrent pulmonary infections and bronchiectasis. Transplantation of normal thymus tissue into the patient and administration of thymus extracts have been of no therapeutic value. The only therapy centers on the control of infections.

Metachromatic Leukodystrophy (Aryl Sulfatase Deficiency)

This is another of the lysosomal (sphingolipid) storage diseases ([Table 37-3](#)). The basic abnormality, localized in chromosome 22, is the absence of the enzyme aryl sulfatase A, a deficiency of which prevents the conversion of sulfatide to cerebroside (a major component of myelin) and results in an accumulation of the former. The disease is transmitted as an autosomal recessive trait and usually becomes manifest between the first and fourth years of life (variants have their onset in the

congenital period, in late childhood, and even in adult life). Variability of gene mutation accounts for the different forms. The disease is characterized clinically by *progressive impairment of motor function* (gait disorder, spasticity) in combination with reduced output of speech and *mental regression*. At first the tendon reflexes are usually brisk, but later, as the peripheral nerves become more involved, the *reflexes are decreased and eventually lost*. Or, there may be variable hypotonia and areflexia from the beginning, or spasticity may be present throughout the illness, but with hyporeflexia and slowed conduction velocities. Signs of mental regression may be apparent from the onset or appear after the motor disorder has become established. Later there is impairment of vision, sometimes with squint and nystagmus; intention tremor in the arms and dysarthria; dysphagia and drooling; and optic atrophy (one-third of patients), sometimes with grayish degeneration around the maculae. Seizures are rare, and there are no somatic abnormalities. The head size is usually normal, but rarely there is macrocephaly. Progression to a bedridden quadriplegic state without speech or comprehension occurs over a 1- to 3-year period, somewhat more slowly in late-onset types. The CSF protein is elevated.

There is widespread degeneration of myelinated fibers in the cerebrum ([Fig. 37-6](#)), cerebellum, spinal cord, and peripheral nerves. The presence of metachromatic granules in glial cells and engorged macrophages is characteristic and enables the diagnosis to be made from a biopsy of a peripheral nerve. The stored material, *sulfatide*, stains brown-orange rather than purple with aniline dyes. Sulfatides are also PAS-positive in frozen sections.

Figure 37-6 Metachromatic leukodystrophy. T2-weighted axial MRI of a 3-year-old boy. Abnormal high signal intensity involves the entire centrum ovale but spares the subcortical arcuate fibers. (From Lee SH, Rao K, Zimmerman RA: *Cranial MRI and CT*, 3rd ed. New York, McGraw-Hill, 1992, by permission.)

The diagnostic laboratory findings, in addition to the MRI and histologic changes, are an elevated CSF protein (75 to 250 mg/dL) and a *marked increase in sulfatide in urine and an absence of aryl sulfatase A* in white blood cells, in serum, and in cultured fibroblasts. Assays of aryl sulfatase A activity in cultured fibroblasts and amniocytes permit the identification of carriers and prenatal diagnosis of the disease.

Treatment with enzyme replacement or bone marrow transplantation is being tried. Marrow transplant appears to be of no benefit once the patient becomes symptomatic, but it may be useful in the treatment of an asymptomatic sibling of an index case.

The differential diagnosis of this leukodystrophy is from neuroaxonal dystrophy (see below), cases of early-onset inherited polyneuropathy, late-onset Krabbe disease, and childhood forms of Gaucher disease and Niemann-Pick disease. A *variant of metachromatic leukoencephalopathy*, due to a deficiency of the isoenzymes of aryl sulfatase A, B, and C, was described by [Austin in 1973](#). He called it “multiple sulfatase deficiency.” The neurologic manifestations resemble those of metachromatic leukodystrophy, but, in addition, there are facial and skeletal changes similar to those of a mucopolysaccharidosis. Deafness, hepatic enlargement, ichthyosis, and beaking of lumbar vertebrae are additional findings in some cases. Metachromatic material is found in the urinary sediment. Pathologically, in addition to metachromasia of degenerating white matter in cerebrum and peripheral nerve, there may be storage material, like that found in the gangliosidoses in neurons. Granules are demonstrable in neutrophilic leukocytes. There has also been described a state of “aryl sulfatase pseudo-deficiency,” which exists as a polymorphism in about 7 percent of Europeans and makes the point that low enzyme levels alone are insufficient to express a phenotype of metachromatic leukodystrophy.

Forms of metachromatic leukodystrophy developing in adult years are discussed further on.

Neuroaxonal Dystrophy (Degeneration)

This is a rare disease, inherited as an autosomal recessive trait. In the largest group of cases (77 collected by [Aicardi and Castelein](#)), the onset was near the beginning of the second year in 50 patients and before the third year in all instances. The clinical constellation comprised psychomotor deterioration (loss of ability to walk, stand, sit, and speak), marked hypotonia but brisk reflexes and Babinski signs, and progressive blindness with optic atrophy but normal retinae. Seizures, myoclonus, and extrapyramidal signs were rare. Loss of sensation was found later in some cases. Terminally, bulbar signs, spasticity, and decerebrate rigidity often supervened. The course was relentlessly progressive, with fatal issue in a decorticate state in 3 to 8 years. There were no abnormalities of the liver and spleen and no facial or skeletal changes.

Pathologic examination reveals eosinophilic spheroids of swollen axoplasm in the posterior columns and nuclei of Goll and Burdach and in Clarke's column, substantia nigra, subthalamic nuclei, central nuclei of brainstem, and cerebral cortex. There is cerebellar atrophy, affecting the granule cell layer predominantly, and increased iron-containing pigment in the basal ganglia (like that observed in Hallervorden-Spatz disease).

The CT scans and CSF are normal, and there are no biochemical or blood cell abnormalities. After the age of 2 years, however, the EEG shows characteristic high-amplitude fast rhythms (16 to 22 Hz). Evoked responses may be abnormal. Nerve conduction velocities are normal despite EMG evidence of denervation. The diagnosis can be reliably established during life by electron microscopic examination of skin and conjunctival nerves, which show the characteristic spheroids within axons.

There is a later-onset form of the disease in which the course is more protracted and the neurologic manifestations (rigidity and spasticity, cerebellar ataxia, and myoclonus) are more pronounced. In these cases the mental regression is slow. Vision may be retained but tapetoretinal degeneration has been documented. Some of the late-onset cases are indistinguishable from Hallervorden-Spatz disease (page 1029).

Late Infantile and Early Childhood Gaucher Disease

As stated earlier (page 997), Gaucher disease usually develops in early infancy, but some cases, so-called Gaucher disease type III, may begin in childhood, between 3 and 8 years of age. The clinical picture is variable and combines features of infantile Gaucher disease—such as abducens palsies, dysphagia, trismus, rigidity of the limbs, and dementia—with features of the late childhood–early adult form, such as palsies of horizontal gaze, diffuse myoclonus, generalized seizures, and a chronic course ([Winkelman et al](#)). The diagnosis is established by the finding of splenomegaly, Gaucher cells, glucocerebroside storage, and deficient activity of glucocerebrosidase in leukocytes or cultured fibroblasts.

Late Infantile–Early Childhood Niemann-Pick Disease

A number of cases of subacute or chronic neurovisceral storage diseases with early signs of hepatosplenomegaly and later signs (2 to 4 years) of neurologic involvement have been described. Crocker and Farber classified them as types III and IV Niemann-Pick disease. Others have classified them as types C and D, although it is now generally agreed that they are best considered a single entity.

The neurologic disorder consists of progressive dementia, dysarthria, ataxia, rarely extrapyramidal signs (choreoathetosis), and *paralysis of horizontal and vertical gaze*, the latter being a distinguishing feature. On attempting to look to the side, some of the patients make head-thrusting movements of the same type that one observes in ataxia-telangiectasia (page 1011) and the oculomotor apraxia of Cogan (page 1080). Lateral eye movements are full on passive movement of the head (oculocephalic maneuver). Convergence is also deficient. A special syndrome called *juvenile dystonic lipidosis* is characterized by extrapyramidal symptoms and paralysis of vertical eye movements. The syndrome of the “sea-blue histiocyte” (liver, spleen, and bone marrow contain histiocytes with sea-blue granules)—in which

iduronate sulfatase.

Sanfilippo Disease This form, or MPS III, expresses itself clinically between 2 and 3 years of age, with progressive intellectual deterioration. The patients are of short stature, but in other respects the physical changes are fewer and less severe than in the Hunter and Hurler syndromes. Three and possibly four types of Sanfilippo disease, designated A, B, C, and D, are distinguished on the basis of their enzymatic defects ([Neufeld and Muenzer](#)). All subtypes are phenotypically similar, and all of them may excrete excessive amounts of heparan sulfate in the urine.

Morquio Disease This form of the disease, MPS IV, is characterized by marked *dwarfism* and *osteoporosis*. Skeletal deformity and compression of the spinal cord and medulla are constant threats, because of hypoplasia of the odontoid process and atlantoaxial dislocation and thickening of the dura around the cervical cord and inferior surface of the cerebellum. Intelligence is affected only slightly or not at all. *Corneal opacities may be present*. Patients excrete large amounts of keratan sulfate in the urine; two types of enzymatic deficiency have been identified ([Neufeld and Muenzer](#)).

Maroteaux-Lamy Disease This syndrome, MPS VI, includes severe skeletal deformities (short stature, anteriorly beaked vertebrae) but *normal intelligence*. Several of our cases have had a cervical pachymeningitis with spinal cord compression and hydrocephalus during adult life. Spinal cord function improved with cervical decompression and the hydrocephalus with ventriculoatrial shunting ([Young et al](#)). Hepatosplenomegaly is often present. Large amounts of dermatan sulfate are excreted in the urine, as a result of an *aryl sulfatase B deficiency*.

b-Glucuronidase Deficiency (Sly Disease) This (MPS VII) is a rare type of mucopolysaccharidosis, the clinical features of which have yet to be sharply delineated. Short stature, progressive thoracolumbar gibbus, hepatosplenomegaly, and the bony changes of dysostosis multiplex (as in the Hurler type) are the main clinical features. There is excessive excretion of dermatan and heparan sulfate, the result of a deficiency of b-glucuronidase.

Attempts to treat the mucopolysaccharidoses by replacement therapy (plasma and leukocytes), bone marrow transplantation, and gene transfer are in progress.

Mucolipidoses and Other Diseases of Complex Carbohydrates (Sialidoses; Oligosaccharidoses)

In recent years several new diseases have been described in which there is an abnormal accumulation of mucopolysaccharides, sphingolipids, and glycolipids in visceral, mesenchymal, and neural tissues, due to an α -N-acetylneuraminidase defect. In some types there is an additional deficiency of b-galactosidase. All are autosomal recessive diseases that manifest many of the clinical features of Hurler disease, but—in contrast to the mucopolysaccharidoses—normal amounts of mucopolysaccharides are excreted in the urine. Frequently, G_{M1} gangliosidosis, described above, is also classified with the mucolipidoses. The other members of this category are synopsized below and in [Table 37-3](#).

Mucolipidoses At least three and possibly four closely related forms have been described. In mucolipidosis I (*lipomucopolysaccharidosis*), the morphologic features are those of gargoylism, with slowly progressive mental retardation. Cherry-red spots in the maculae, corneal opacities, and ataxia have been noted in some patients. Vacuolation of lymphocytes, marrow cells, hepatocytes, and Kupffer cells in the liver and metachromatic changes in the sural nerve have been described.

In *mucolipidosis II (“I-cell” disease)*, the most common of the mucolipidoses, there is usually an early onset of psychomotor retardation, but often this does not appear until the second or third decade. *Abnormal facies* and *periosteal thickening (dysostosis multiplex)*, like that of G_{M1} gangliosidosis and Hurler disease) are characteristic. *Gingival hyperplasia* is prominent, and the *liver* and *spleen are enlarged*; but deafness is not found and corneal opacities are slower to develop. Tonic-clonic seizures are frequent in older patients. In most cases, death from heart failure occurs by the third to eighth year. There is a typical vacuolation of lymphocytes, Kupffer cells, and cells of the renal glomeruli. Bone marrow cells are also vacuolated and contain refractile cytoplasmic granules (hence the designation *inclusion-cell*, or *I-cell, disease*). A deficiency of several lysosomal enzymes required for the catabolism of mucopolysaccharides, glycolipids, and glycoproteins has been described.

In *mucolipidosis III (pseudo-Hurler polydystrophy)*, the biochemical abnormalities are like those of I-cell disease, but there are clinical differences. In the pseudo-Hurler type, symptoms do not appear until 2 years of age or later and are relatively mild. Retardation of growth, fine corneal opacities, and valvular heart disease are the major manifestations.

Yet another variant, so-called mucolipidosis IV, has been described (see [Tellez-Nagel et al](#)). Here, clouding of the corneas is noticed soon after birth, and profound retardation is evident by 1 year of age. Skeletal deformities, enlargement of liver and spleen, seizures, or other neurologic abnormalities are notably lacking. Ultrastructural examination of conjunctival and skin fibroblasts has demonstrated lysosomal inclusions of material similar to lipids and mucopolysaccharides which remain to be further characterized.

Mannosidosis This is another rare hereditary disorder with poorly differentiated symptomatology. The onset is in the first 2 years, with *Hurler-like facial and skeletal deformities*, *mental retardation*, and slight motor disability. Corticospinal signs, loss of hearing, variable degrees of gingival hyperplasia, and spoke-like opacities of the lens (but no diffuse corneal clouding) may be present. The liver and spleen are enlarged in some cases. Radiographs show beaking of the vertebral bodies and poor trabeculation of long bones. Vacuolated lymphocytes and granulated leukocytes are present and aid in diagnosis. The urinary mucopolysaccharides are normal. *Mannosiduria is diagnostic*, caused by a defect in α -mannosidase. Mannose-containing oligosaccharides accumulate in nerve cells, spleen, liver, and leukocytes ([Kistler et al](#)).

Fucosidosis This also is a rare autosomal recessive disorder, with neurologic deterioration beginning usually at 12 to 15 months and progressing to spastic quadriplegia, decerebrate rigidity, severe psychomotor regression, and death within 4 to 6 years. *Hepatomegaly*, splenomegaly, enlarged salivary glands, thickened skin, excessive sweating, normal or typical gargoyle facies, *beaking of the vertebral bodies*, and vacuolated lymphocytes are the main features. A variant of this disease has been described with slower progression and survival into late childhood and adolescence and even into adult life ([Ikeda et al](#)). The latter type is characterized by mental and motor retardation, along with the corneal opacities, coarse facial features, skeletal deformities of gargoylism, and dermatologic changes of Fabry disease (angiokeratoma corporis diffusum), but no hepatosplenomegaly. The basic abnormality in both types is a lack of lysosomal L-fucosidase, resulting in accumulation of fucose-rich sphingolipids, glycoproteins, and oligosaccharides in cells of the skin, conjunctivae, and rectal mucosa.

Aspartylglycosaminuria This disease is characterized by the early onset of psychomotor regression; delayed, inadequate speech; severe behavioral abnormalities (*bouts of hyperactivity* mixed with apathy and hypoactivity or psychotic manifestations); progressive dementia; clumsy movements; corticospinal signs; corneal clouding (rare); retinal abnormalities and cataracts; coarse facies including low bridge of the nose, epicanthi, thickening of the lips and skin; enlarged liver; and abdominal hernias in some. Radiographs show minimal *beaking of the vertebral bodies*, and vacuolated lymphocytes are seen in the blood.

The pattern of inheritance in this entire group of diseases is, as already stated, probably autosomal recessive. Diagnostic methods applicable to amniotic fluid and cells are being developed so that prenatal diagnosis will be possible, prompted often by the occurrence of the disease in an earlier child. Neurons are vacuolated rather than stuffed with granules, much like the lymphocytes and liver cells. The specific biochemical abnormalities, as far as they are known, are indicated in [Table 37-3](#).

Cockayne Syndrome

This disorder is probably inherited as an autosomal recessive trait. The onset is in late infancy, after apparently normal earlier development. The main clinical findings are *stunting of growth*, evident by the second and third years; *photosensitivity of the skin*; microcephaly; *retinitis pigmentosa*, *cataracts*, blindness, and pendular nystagmus; nerve deafness; *delayed psychomotor* and speech development; spastic weakness and *ataxia of limbs* and gait; occasionally athetosis; amyotrophy with abolished reflexes and reduced nerve conduction velocities; wizened face, sunken eyes, prominent nose, prognathism, anhydrosis, and poor lacrimation (resembling progeria and bird-headed dwarfism). Some cases show calcification of the basal ganglia. The CSF is normal, and there are no diagnostic biochemical findings.

Pathologic examination reveals a small brain, striatocerebellar calcifications, leukodystrophy like that of Pelizaeus-Merzbacher disease, and a severe cerebellar cortical atrophy. The peripheral nerve changes are those of a primary segmental demyelination. The pathogenesis is unknown. The variability in clinical and pathologic manifestations of reported cases suggests that not all of them are representative of the same disease.

Rett Syndrome

This syndrome is mentioned here because for many years, on the basis of psychomotor regression after a period of normal development, it was presumed to have a metabolic basis (urea cycle defect). However, neither this metabolic defect nor any other has ever been substantiated. Recently, the responsible gene mutation has been discovered. The syndrome is discussed fully in [Chap. 38](#), with other forms of developmental mental retardation and autism.

Other Diseases of Late Infancy and Early Childhood

Globoid cell leukodystrophy (Krabbe), subacute necrotizing encephalomyelopathy (Leigh), and Gaucher disease may also begin in late infancy or early childhood. They have been described in the preceding section of this chapter. Familial striatocerebellar calcification ([Fahr](#) disease) and Lesch-Nyhan disease may also become manifest in this age period, but they usually have a later onset and are therefore described with the diseases of later childhood in the section that follows.

Diagnosis of Metabolic Diseases of Late Infancy and Early Childhood

This group of metabolic disorders presents many of the same diagnostic problems as those of early infancy. The flowchart ([Fig. 37-4](#)), which divides these disorders into dysmorphic, visceromegalic, and purely neurologic groups, is equally serviceable in the differential diagnosis of both groups. Also, as with the early infantile diseases, certain clusters of neurologic, skeletal, dermal, ophthalmic, and laboratory findings are highly distinctive and often permit the identification of a particular disease. These signs are listed below:

1. Evidence of involvement of peripheral nerves (weakness, hypotonia, areflexia, sensory loss, reduced conduction velocities) in conjunction with lesions of the central nervous system—metachromatic leukodystrophy, Krabbe leukodystrophy, neuroaxonal dystrophy, and Leigh disease (rare)
2. Ophthalmic signs
 - a. Corneal clouding—several of the mucopolysaccharidoses (Hurler, Scheie, Morquio, Maroteaux-Lamy), mucopolipidoses, tyrosinemia, aspartylglycosaminuria (rare)
 - b. Cherry-red macular spot—G_{M2} gangliosidosis, G_{M1} gangliosidosis (half the cases), lipomucopolysaccharidosis, occasionally Niemann-Pick disease
 - c. Retinal degeneration with pigmentary deposits—Jansky-Bielschowsky lipid storage disease, G_{M1} gangliosidosis, syndrome of sea-blue histiocytes
 - d. Optic atrophy and blindness—metachromatic leukodystrophy, neuroaxonal dystrophy
 - e. Cataracts—Marinesco-Sjögren syndrome, Fabry disease, mannosidosis
 - f. Telangiectasia and ocular apraxia—ataxia-telangiectasia, Niemann-Pick disease
 - g. Impairment of vertical eye movements—late infantile Niemann-Pick disease, juvenile dystonic lipidosis, sea-blue histiocyte syndrome, Wilson disease
 - h. Jerky eye movements, limited abduction—late infantile Gaucher disease
3. Extrapyrarnidal signs—late-onset Niemann-Pick disease (rigidity, abnormal postures), juvenile dystonic lipidosis (dystonia, choreoathetosis), Rett, ataxia-telangiectasia (athetosis), Sanfilippo mucopolysaccharidosis, type I glutaric acidemia, Wilson disease, Segawa dopa-responsive dystonia
4. Facial dysmorphism—Hurler, Scheie, Morquio, and Maroteaux-Lamy forms of mucopolysaccharidosis, aspartylglycosaminuria, mucopolipidoses, G_{M1} gangliosidosis, mannosidosis, fucosidosis (some cases), multisulfatase deficiencies ([Austin](#)), some mitochondrial disorders
5. Dwarfism, spine deformities, arthropathies—Hurler, Morquio, and other mucopolysaccharidoses, Cockayne syndrome
6. Enlarged liver and spleen—Niemann-Pick disease, Gaucher disease, all mucopolysaccharidoses, fucosidosis, mucopolipidoses, G_{M1} gangliosidosis
7. Alterations of skin—photosensitivity (Cockayne syndrome and one form of porphyria); papular nevi and angiokeratoma (Fabry disease, fucosidosis); telangiectasia of ears, conjunctiva, chest (ataxia-telangiectasia); ichthyosis ([Sjögren-Larsen](#) disease, caused by fatty alcohol dehydrogenase deficiency); plaque-like lesions in Hunter syndrome
8. Beaked thoracolumbar vertebrae—all mucopolysaccharidoses, mucopolipidoses, mannosidosis, fucosidosis; aspartylglycosaminuria, multiple sulfatase deficiencies
9. Deafness—mucopolysaccharidoses, mannosidosis, Cockayne syndrome
10. Hypertrophied gums—mucopolipidoses, mannosidosis
11. Vacuolated lymphocytes—all mucopolysaccharidoses, mucopolipidoses, mannosidosis, fucosidosis
12. Granules in neutrophils—all mucopolysaccharidoses, mucopolipidoses, mannosidosis, fucosidosis, multiple sulfatase deficiencies

In our experience the most difficult diagnostic problems in this age period are raised by neuroaxonal dystrophy, metachromatic leukodystrophy, the mitochondrial disorder subacute necrotizing encephalomyelopathy (Leigh disease), some cases of lipofuscinosis, and the late form of G_{M1} gangliosidosis. In none of these diseases is the clinical picture entirely stereotyped. Most helpful in the clinical diagnosis of neuroaxonal dystrophy is the onset, at 1 to 2 years of age, of severe hypotonia with retained reflexes and Babinski signs, early visual involvement without retinal changes, lack of seizures, normal CSF, physiologic evidence of denervation of muscles, fast-frequency EEG, normal CT scan, and *N*-acetylgalactosaminidase deficiency in cultured fibroblasts. Metachromatic leukodystrophy can be excluded if the CSF protein is normal and if nerve conduction velocities and enzymatic studies of leukocytes and fibroblasts are normal. Similar criteria enable one to rule out G_{M1} gangliosidosis. Leigh disease may begin at the same age, with hypotonia and optic atrophy, but abnormalities of ocular movement and respiration appear early; in many cases the lactic acidosis and pyruvate decarboxylase defect will corroborate the diagnosis. Also in Leigh disease, CT scanning and MRI may disclose hypodense lesions in the basal ganglia and brainstem, in contrast to the normal CT scan in neuroaxonal dystrophy. In metachromatic leukodystrophy, the cerebral white matter shows a diffusely decreased attenuation and the MR images are striking ([Fig. 37-6](#)). Lipofuscinosis cannot always be diagnosed accurately; curvilinear bodies in nerve twigs, endothelial cells in skin biopsies, and the recently discovered gene mutations are the best laboratory tests.

INHERITED METABOLIC ENCEPHALOPATHIES OF LATE CHILDHOOD AND ADOLESCENCE

Unavoidably, one must refer here to certain inherited metabolic diseases already described that permit survival into late childhood and adolescence as well as to diseases that begin in adolescence or adult life after a normal childhood. There is a tendency for them to be less severe and less rapidly progressive, an attribute shared by many diseases with a dominant mode of inheritance. Nonetheless, there are diseases, such as Wilson disease, in which the onset of neurologic symptoms occurs after the 10th year and in rare instances after the 30th year, and the mode of inheritance is recessive in type. However, in the latter instance, the basic abnormality has existed since early childhood in the form of a ceruloplasmin deficiency with early cirrhosis and splenomegaly; only the neurologic disorder is of late onset. This brings us to another principle—that the pathogenesis of the cerebral lesion may involve a factor or factors once removed from the underlying biologic abnormality, in this case cirrhosis of the liver.

Genetic heterogeneity poses another problem with respect to both the clinical and biochemical findings. It is well established that a single clinical phenotype such as the one seen in Hurler disease can be the expression of a number of different alleles of a given gene mutation. Conversely, a number of different clinical phenotypes may be based on different degrees of the same enzyme deficiency. One must, therefore, not rely solely on clinical appearances for diagnosis but always combine them with biochemical tests and molecular genetic studies for confirmation. No one of these lines of data is sufficient for classification of disease.

The diseases in this category are probably of greater interest to neurologists than the preceding ones, for they more consistently cause familiar neurologic abnormalities such as epilepsy, polymyoclonus, dementia, cerebellar ataxia, choreoathetosis, dystonia, tremor, spastic-ataxic paraparesis, blindness, deafness, and stroke. These manifestations appear much the same in late childhood and adolescence as they do in adult life, and the neurologist whose experience has been mainly with adult patients feels quite comfortable with them.

Diseases in this age period have a diversity of manifestations, yet each disease tends to have a certain characteristic pattern of neurologic expression, as though the pathogenetic mechanism were acting selectively on particular systems of neurons. Such affinities between the disease process and certain anatomic structures raise the question of *pathocllisis*, i.e., specific vulnerability of particular neuronal systems to certain morbid agents. Stated another way, for each disease there is a common and relatively stereotyped clinical syndrome and a small number of variants; conversely, certain other symptoms and syndromes are rarely observed with a given disease. At the same time, however, it is clear that more than one disease may cause the same syndrome.

In deference to these principles, *the diseases in this section are grouped according to their most common mode of clinical expression*, as follows:

1. The progressive cerebellar ataxias of childhood and adolescence
2. The familial polymyoclonias and epilepsies
3. Extrapyrarnidal syndromes of parkinsonian type
4. The syndrome of dystonia and generalized choreoathetosis

5. The syndrome of bilateral hemiplegia, cerebral blindness and deafness, and other manifestations of focal cerebral disorder
6. Strokes in association with inherited metabolic diseases
7. Metabolic polyneuropathies
8. Personality changes and behavioral disturbances as manifestations of inherited metabolic diseases

It is advantageous to be familiar with these groupings, for a knowledge of them, like the age of onset and gray and white matter distinctions in diseases of earlier onset, facilitates clinical diagnosis. Variants seen personally by the authors are mentioned in the descriptions of the diseases themselves. One word of caution—it is a mistake to assume that the diseases in these categories affect one and only one particular part of the nervous system or to assume that they are exclusively neurologic. Once the biochemical abnormality is discovered, it is usually found to implicate cells of certain nonneurologic tissues as well; whether or not the effects of such involvement become symptomatic is often a quantitative matter. Also, one encounters mixed neurologic syndromes in which tremor, myoclonus, cerebellar ataxia, and choreoathetosis are present in various combinations; sometimes it is difficult to decide whether a movement disorder is of one type or another.

The Progressive Cerebellar Ataxias of Late Childhood and Adolescence

In the preceding section it was pointed out that there is a large group of diseases, some with (but most without) a known metabolic basis, in which an acute, episodic, or chronic cerebellar ataxia becomes manifest in early childhood. Here the discussion of the cerebellar ataxias is continued, with reference to those forms that begin in late childhood and adolescence. In these later age periods the number of ataxias of proven metabolic type diminishes markedly. Most of them, of chronic progressive type, are part of the late-onset lipid storage diseases. Of the other cerebellar ataxias of late childhood and adolescence, only the Bassen-Kornzweig acanthocytosis and a genetic fault in vitamin E metabolism fall into the category of a truly metabolic disease—and one could perhaps add late-onset G_{M2} gangliosidosis (page 1024), Refsum disease, ataxia-telangiectasia, and prolonged vitamin E deficiency. Refsum disease is so clearly a polyneuropathy (cerebellar features only in exceptional cases) that it is presented in [Chap. 46](#). Ataxia-telangiectasia is usually encountered in late childhood, but the ataxia may begin as early as the second year of life; therefore it has been described in the preceding section with the ataxias of early childhood. The effect of vitamin E deficiency on the nervous system is described on page 1224.

Doubtless, many of the progressive forms of cerebellar ataxia now classified as degenerative and described in [Chap. 39](#) will soon be proved to have an underlying biochemical pathogenesis and will logically be placed here, with the metabolic diseases. At present, when faced with a progressive ataxia of cerebellar type, the reader should consult both this chapter and [Chap. 39](#).

The *acute forms of cerebellar ataxia* that occur in late childhood and adolescence are essentially nonmetabolic, being observed as part of postinfectious encephalomyelitis (page 797); in postanoxic, postmeningitic, and posthyperthermic states; and with certain drug intoxications. And with pure cerebellar ataxias of this age period, postinfectious cerebellitis, cerebellar tumors (medulloblastomas, astrocytomas, hemangioblastomas, and ganglioneuromas of Lhermitte-Duclos) must always be considered. MRI usually establishes the correct diagnosis.

Bassen-Kornzweig Acanthocytosis (Abetalipoproteinemia) This disease, first described by [Bassen and Kornzweig in 1950](#), excited great interest, for it gave promise of a breakthrough into a hitherto obscure group of “degenerative” disorders. In the 15-year period that followed the original report, less than a dozen cases were recorded, and several of the reports were based on the study of the same case. In our experience, it is a rare disease. We have seen only three cases. The resemblance to Friedreich ataxia is not so close that an experienced clinician would be likely to confuse the two.

The inheritance of this disease is autosomal recessive in type. The initial symptoms, occurring between 6 and 12 years (range, 2 to 17 years), are weakness of the limbs with areflexia and an ataxia of sensory (tabetic) type, to which a cerebellar component is added later (see also page 1421). Steatorrhea, raising the suspicion of celiac disease, often precedes the weak, unsteady gait. Later, in more than half the patients, vision may fail because of retinal degeneration (similar to retinitis pigmentosa). Kyphoscoliosis, pes cavus, and Babinski signs are other elements in the clinical picture. The neurologic disorder is relatively slowly progressive—by the second to third decade, the patient is usually bedridden.

The diagnostic laboratory findings are spiky or thorny red blood cells (acanthocytes), low sedimentation rate, and a marked reduction in the serum of low-density lipoproteins (cholesterol, phospholipid, and b-lipoprotein levels are all subnormal). Pathologic study has revealed the presence of foamy, vacuolated epithelial cells in the intestinal mucosa (causing absorption block); diminished numbers of myelinated nerve fibers in sural nerve biopsies, depletion of Purkinje and granule cells in all parts of the cerebellum; loss of fibers in the posterior columns and spinocerebellar tracts; loss of anterior horn and retinal ganglion cells; muscle fiber loss; and fibrosis of the myocardium. It has been proposed that the basic defect is an inability of the body to synthesize the proteins of cell membranes, because of the impaired absorption of fat through the mucosa of the small intestine. Vitamin E deficiency may be a pathogenic factor, since the administration of a low-fat diet and high doses of vitamins A and E may prevent progression of the neurologic disorder ([Illingworth et al](#)).

Familial Hypobetalipoproteinemia This is a well-described disease, resembling abetalipoproteinemia, in which there is hypocholesterolemia, acanthocytosis of red blood corpuscles, retinitis pigmentosa, and a pallidal atrophy (HARP syndrome). Inheritance is autosomal dominant, and heterozygotes may exhibit some part of the syndrome. Fat droplets may be seen in the jejunal mucosa, indicating malabsorption. Cases have been reported from Europe, Asia, and the United States. Treatment consists of restriction of dietary fat and supplements of vitamin E.

An adult form of acanthocytosis and hereditary chorea and dystonia has also been recognized, but evidence of lipid malabsorption is lacking. This disease is described in [Chap. 39](#).

There are doubtless many other conditions of metabolic type in which cerebellar ataxia figures importantly in the clinical picture. Some of these are associated with polymyoclonus and cherry-red macular spots (sialidosis or neuraminidosis; see below). Cerebellar ataxia is a prominent feature of Unverricht- Lundborg (Baltic) disease and Lafora-body disease. The Cockayne syndrome and Marinesco-Sjögren disease, already described under “Inherited Metabolic Diseases of Late Infancy and Early Childhood,” persist into later childhood and adolescence or may even have their onset in this later period. In cerebrotendinous xanthomatosis (see further on), spastic weakness and pseudobulbar palsy are combined with cerebellar ataxia. Prader-Willi children have a broad-based gait and are clumsy in addition to being obese, genitally deficient, and diabetic. One family of five males with a syndrome of hyperuricemia, spinocerebellar ataxia, and deafness has been reported by [Rosenberg and colleagues](#), and several other variants of defective purine and pyrimidine metabolism fit into this category; the enzymatic defect of Lesch-Nyhan disease was not present, however. Marsden and coworkers have observed cerebellar ataxia beginning in late childhood, as an expression of adrenoleukodystrophy (see below). The familial syndrome of neurodegeneration, ataxia, and retinitis pigmentosa (NARP, page 1043) caused by a mitochondrial genome mutation that impairs ATP synthase can closely mimic the Marinesco-Sjögren syndrome.

Hereditary Paroxysmal Cerebellar Ataxia This not uncommon syndrome of periodic ataxia, akin to the familial paroxysmal choreoathetosis and periodic dystonia described in [Chap. 4](#), is inherited as an autosomal dominant trait. The gene for hereditary paroxysmal ataxia, which codes for a portion of the calcium channel, maps to chromosome 19p ([Vahedi et al](#)). It has its onset in childhood or early adult life and takes the form of disabling episodic attacks of ataxia, nystagmus, and dysarthria, each attack lasting a few minutes or a few hours. Between attacks the patients are asymptomatic or show only a mild nystagmus or minimal clumsiness. The attacks can be prevented by the administration of acetazolamide, 250 mg tid, as had been noted originally by [Griggs et al](#). These characteristics apply to what is now termed *familial episodic ataxia* type 2; a rarer type 1 is related to a mutation in the voltage-gated potassium channel and is associated with myokymia and epilepsy.

The Familial Polymyoclonias

As stated in [Chap. 6](#), the term *myoclonus* is applied to many conditions that are not at all alike but share a single clinical feature—a multitude of exceedingly brief, random, arrhythmic twitches of parts of muscles, entire muscles, or groups of muscles. Myoclonic jerks differ from chorea by virtue of their brevity (15 to 50 ms). Notably, both phenomena are considered to be symptomatic of “gray matter” diseases.

Myoclonus or polymyoclonus may, in certain conditions, stand alone as a relatively pure syndrome. In other cases, it is mixed with epilepsy or athetosis and dystonia, discussed further on. Most often, myoclonus is associated with cerebellar ataxia, for which reason it is being considered here, juxtaposed with the progressive cerebellar ataxias. The many acquired forms of polymyoclonus, such as subacute sclerosing panencephalitis, have been mentioned in [Chap. 6](#). In this chapter we are concerned only with those of known or presumed metabolic origin.

Myoclonic Encephalopathy of Infants Under this title Kinsbourne originally described a form of widespread, continuous myoclonus (except during deep sleep) affecting male and female infants whose development had been normal until the onset of the disease at the age of 9 to 20 months. The myoclonus evolves over a

week or less, affects all the muscles of the body, and interferes seriously with all the natural muscular activities of the child. The eyes are notably affected by rapid (up to 8 per second), irregular conjugate movements (“dancing eyes” of an opsoclonic type). The child is irritable and speech may cease. All laboratory tests are normal.

Adrenocorticotrophic hormone and dexamethasone, the latter in doses of 1.5 to 4.0 mg/day, suppress the myoclonus and permit developmental progress. Some patients have recovered from the myoclonus and have been mentally slow and mildly ataxic afterward. Others have required corticosteroid therapy for 5 to 10 years, with relapse whenever it is discontinued. Ordinary anticonvulsants seem to have no effect. The pathologic basis of the polymyoclonus has not been defined.

A similar syndrome has been observed in conjunction with neuroblastoma, rarely with bronchogenic and other occult carcinomas, and as a transient illness of unknown (possibly viral) cause in young adults ([Baringer et al](#); see page 1087).

In a broader survey of the pediatric opsoclonus-myoclonus syndrome, Pranzatelli and associates reported their experience with 27 cases, some with neural crest tumors, others with viral infections or hypoxic injury (intention myoclonus). In nearly all of their patients there was cerebellar ataxia and mental disorder, and 10 percent had seizures. The CSF was normal. The investigators emphasize the pathogenetic heterogeneity and define a serotonergic type (low levels of 5-hydroxytryptophan and homovanillic acid in the CSF) that responds to 5-hydroxyindole acetic acid.

Familial Progressive Myoclonus Five major categories of familial polymyoclonus of late childhood and adolescence have been delineated: (1) Lafora- or amyloid-body type, (2) juvenile cerebretinal degeneration, (3) cherry-red spot-myoclonus (sialidosis or neuraminidosis), (4) mitochondrial encephalopathy, and (5) a more benign degenerative disease (dyssynergia cerebellaris myoclonica of Hunt). Familial myoclonus may also be a prominent feature of two other diseases—G_{M2} gangliosidosis and Gaucher disease—which occasionally have their onset in this age period.

Lafora-Body Polymyoclonus with Epilepsy This disease, which is inherited as an autosomal recessive trait, was first identified by Lafora in 1911 on the basis of the large basophilic cytoplasmic bodies that were found in the dentate, brainstem, and thalamic neurons. They have been shown by [Yokoi and colleagues](#) to be composed of a glucose polymer (polyglycosan) that is chemically but not structurally related to glycogen. Possibly some of the cases of familial myoclonus epilepsy reported by Unverricht and by [Lundborg](#) were of this type, but since these authors provided no pathologic data, one cannot be sure.

Beginning in late childhood and adolescence (11 to 18 years) in a previously normal individual, the disease announces itself by a seizure, a burst of myoclonic jerks, or both. In about half the cases there are focal (often occipital) seizures. The illness may at first be mistaken for ordinary epilepsy, but within a few months it becomes evident that it is far more serious. The myoclonus becomes widespread and can be evoked by noise, startle, an unexpected tactile stimulus (even the tap of a reflex hammer), excitement, or certain sustained motor activities. An evoked train of myoclonic jerks may progress to a generalized seizure with loss of consciousness. As the disease advances, the myoclonus interferes increasingly with the patient's motor activities until function is seriously impaired. Speech may be marred, much as it is in chorea. Close examination may also reveal an alteration in muscle tone and a slight degree of cerebellar ataxia. At this time, or even before the onset of myoclonus and seizures, the patient may experience visual hallucinations or exhibit irritability, odd traits of character, uninhibited or impulsive behavior, and, ultimately, progressive failure in all cognitive functions. Deafness has been an early sign in a few cases. Rigidity or hypotonia, impaired tendon reflexes, acrocyanosis, and rarely corticospinal tract signs are late findings. Finally the patient becomes cachectic and bedfast and succumbs to intercurrent infection. Most do not survive beyond their 25th birthday. Nonetheless there are isolated reports of Lafora-body disease in which symptoms began as late as 40 years, with death as late as 50 years. These late cases may constitute a separate genetic type.

No abnormalities of the blood, urine, or CSF have been detected. The EEG shows diffuse slow waves and spikes as well as focal or multifocal discharges. Altered hepatocytes with homogeneous PAS-positive bodies that displace the nuclei have been observed in both the presymptomatic and symptomatic stages of the disease. These inclusions have been seen in skin and liver biopsies even though liver function tests were normal. Neuropathologic examinations have shown a slight loss of granule and Purkinje cells and loss of neurons in the dentate nuclei, inner segment of globus pallidus, and cerebral cortex in addition to the Lafora bodies. The latter may also be seen in the retina, cerebral cortex, myocardium, and striated muscles. Anticonvulsant drugs, especially methsuximide and valproic acid, help in the control of the seizures but have no effect on the basic process.

Polyglycosan Body Disease This is another closely related disease, reviewed by [Robitaille and coworkers](#), in which glycosamine bodies are found in the central and peripheral nervous system. The clinical syndrome included dementia, chorea, and amyotrophy with or without sensory loss in the limbs. Similar bodies were found in liver and heart. This progressive disease beginning in adult life was attributed to the accumulation of polymers of glucose. Diagnosis is confirmed by the finding of these bodies in the axons of peripheral nerves or liver cells.

Juvenile Cerebretinal Degeneration (Ceroid Lipofuscinosis) As stated earlier, this is one of the most variable forms of the lipidoses. The salient clinical features of the later-onset types are severe myoclonus, seizures, and visual loss. In the juvenile type, the first lesions are seen in the maculae; they appear as yellow-gray areas of degeneration and stand in contrast to the cherry-red spot and the encircling white ring of Tay-Sachs disease. At first the particles of pigment are fine and dust-like; later they agglomerate to resemble more the bone-corpuscular shapes of retinitis pigmentosa. The liver and spleen are not enlarged, and there are no osseous changes. The usual development of these and other manifestations of the disease was outlined by [Sjögren](#), who studied a large number of the late infantile and juvenile types of cases in Sweden. He divided the illness into five stages:

1. Visual impairment, sometimes preceding retinal changes by months.
2. After approximately 2 years, the onset of generalized seizures and myoclonus, often with irritability, poor control of emotions, and stuttering, jerky speech.
3. Gradual intellectual deterioration (poor memory, reduced mental activity, inattentiveness). By this stage the movements have usually become slow, stiff, and tremulous, resembling somewhat those of Parkinson disease—to which are added elements of cerebellar ataxia and intention tremor, coming in this way to resemble Wilson disease.
4. Stage of severe dementia in which the patient needs assistance to walk, no longer speaks, and may scream when disturbed or forced to move. The muscles are wasted, though the tendon reflexes are lively and the plantar reflexes are extensor.
5. Finally the patient lies curled up in bed, blind and speechless, with strong extensor plantar reflexes, occasionally adopting dystonic postures. Mercifully the illness ends in 10 to 15 years.

In the early stages the EEG picture of random, high-voltage, triphasic waves is diagnostic; later, as the seizures and myoclonic jerks become less frequent and finally cease, only delta waves remain. The electroretinographic waveforms are lost once the retina is affected. The lateral ventricles are slightly dilated in CT scans and on MRI. The CSF is normal. Diagnosis can be confirmed by electron microscopic study of biopsy material, particularly of the eccrine sweat glands of the skin. A defective membrane protein has been identified that shows a curvilinear “fingerprint” pattern of the inclusion material in the commonest, or classic, juvenile phenotype. A gene mutation has been identified on chromosome 16p.

The *Kufs type of ceroid lipofuscinosis*, which develops later (15 to 25 years), is often unattended by visual or retinal changes and is even slower in its evolution. Personality change and seizures, usually with some degree of myoclonus, are the principal abnormalities. As the disease progresses, cerebellar ataxia, spasticity and rigidity or athetosis, or mixtures thereof, are combined with dementia. Van Bogaert (personal communication) noted that relatives of these patients may have retinal changes without neurologic accompaniments.

Of all the lipidoses, these cerebretinal degenerations have defied biochemical definition. In a few of the early childhood types, mutations of one of several lysosomal enzymes have been identified, as summarized by [Mole](#). As mentioned earlier, Zeman and coworkers have shown that the cytoplasmic inclusions are autofluorescent and give a positive histochemical reaction for ceroid and lipofuscin, but this has not been biochemically differentiated from the similar lipid substance that accumulates in aging cells. In addition to the presence of curvilinear bodies in the cytoplasm of neurons, some in a fingerprint pattern, there is a reduction in type II synapses in the distal parts of the axon. All these changes precede nerve cell loss.

Childhood or Juvenile G_{M2} Gangliosidosis Rarely, instances of the recessive type of G_{M2} gangliosidosis have their onset at this age period. Twenty-four such cases (from 20 kindreds) were found in the medical literature by [Meek and coworkers](#). Ataxia and dysarthria were frequently the presenting symptoms, followed by dementia, dysphagia, spasticity, dystonia, seizures, and myoclonus. Degeneration of anterior horn cells with progressive muscular atrophy may be a feature, although this is more characteristic of the adult-onset variety (see further on). Atypical cherry-red spots are observed in some patients. The biochemical abnormality, i.e., a deficiency of hexosaminidase A, is the same as in Tay-Sachs disease but not as severe or as extensive. Progression of the disease is slow, over a period of many years. Some of our patients are alive at 40 years, the disease having begun in adolescence.

Late Gaucher Disease with Polymyoclonus A type of Gaucher disease is occasionally encountered in which seizures, severe diffuse myoclonus, supranuclear

gaze disorders (slow saccades, saccadic and pursuit horizontal gaze palsies), and cerebellar ataxia begin in late childhood, adolescence, or adult life. The course is slowly progressive. The intellect is relatively spared. The spleen is enlarged. The pathologic and biochemical abnormalities are the same as those of Gaucher disease of earlier onset ([Winkelman et al](#)).

Cherry-Red Spot–Myoclonus Syndrome This is a relatively new and genetically distinct class of disease characterized by the storage of sialidated glycopeptides in tissues; it is due to a neuraminidase deficiency. In some of the patients the onset has been in late childhood or adolescence and in others even later. In addition to the patients reported by [Rapin and coworkers](#), 24 similar cases have been reported in the medical literature, and we have personally observed several such instances.

In the cases of Rapin and colleagues and in two of our own, the first findings were visual impairment with cherry-red macular spots, similar to those seen in Tay-Sachs disease and less consistently in G_{M1} gangliosidosis, Niemann-Pick disease, and metachromatic leukodystrophy. In one case there was severe episodic pain in the hands, legs, and feet during hot weather, reminiscent of Fabry disease. Polymyoclonus followed within a few years and, together with cerebellar ataxia, disabled the patients. Mental function remained relatively normal. Liver and spleen were not enlarged, but storage material was found in the Kupffer cells, neurons of the myenteric plexus, and cerebral neurons, and presumably in cerebellar and retinal ones.

The cases of Thomas and colleagues were young adults, all members of one generation, who had developed dysarthria, intention myoclonus, cerebellar ataxia, and cherry-red macular lesions. Like the cases of Rapin and coworkers, the heredity was autosomal recessive. There was urinary excretion of sialilated oligosaccharides and a sialidase deficiency in cultured fibroblasts. The two patients described by [Tsuji and associates](#) are noteworthy insofar as they were aged 50 and 30 years, respectively. In addition to the macular lesions, polymyoclonia, and cerebellar ataxia, there were gargoylike facial features, corneal opacities, and vertebral dysplasia. These patients also had a neuraminidase (partial b-galactosidase) deficiency.

Dentatorubral Cerebellar Atrophy with Polymyoclonus This progressive degeneration of the cerebellar-dentate efferent system was originally described by Ramsay Hunt under the title of *dyssynergia cerebellaris myoclonica*. The onset is in late childhood; both sexes are vulnerable, and it probably has more than one cause. In Hunt's case, a progressive ataxia was accompanied by a striking degree of action myoclonus. Seizures are infrequent and the intellect is relatively preserved. The neurons of the dentate nuclei and their ascending and descending brainstem axons gradually disappear. Berkovic and associates have studied 84 cases of polymyoclonus, 13 of which conformed to the Hunt syndrome. Of these, 9 proved to have a mitochondrial encephalomyopathy. However, there are other reports ([Tassinari et al](#)) in which muscle biopsies showed no mitochondrial abnormalities. In the series of 30 cases reported by [Marsden and coworkers](#), the onset was usually before the age of 21 years. There were cortical discharges preceding each myoclonic twitch. A clinical or biochemically supported diagnosis could not be made in nearly half of their cases.

We have observed restricted, extremely chronic forms of rhythmic myoclonus that involved only the facial and bulbar muscles. Although this benign familial polymyoclonia has not been associated with any biochemical abnormalities, its association with cellular mitochondrial abnormalities in some cases justifies its inclusion in this chapter rather than with the degenerative diseases. Another mitochondrial disorder, the myoclonic epilepsy ragged red fiber disease (MERRF), begins in the second decade or later with myoclonus and ataxia and enters into the differential diagnosis of this group of diseases. The mitochondrial diseases as a group are considered in the last part of this chapter.

Epilepsies of Hereditary Metabolic Disease

Convulsive seizures may complicate nearly all hereditary metabolic diseases. The seizures may occur at all ages but more frequently in the neonate, infant, or young child than in the older child or adolescent. The seizures take many forms, as discussed in [Chap. 16](#). Most often they are generalized grand mal or partial types; typical petit mal probably does not occur. Some diseases may cause focal seizures, simple or complex partial, before becoming generalized. The combination of series of polymyoclonic jerks progressing to a generalized motor seizure is always highly suggestive of one of the hereditary metabolic diseases. Another highly significant form of presentation is with sensory evoked seizures. The subject of epilepsy and the hereditary metabolic diseases has recently been reviewed by [Sansaricq and colleagues](#).

Extrapyramidal Syndromes with Hereditary Metabolic Disease

Reference is made here to the distinctive motor disorders described in [Chap. 4](#). In the typical parkinsonian syndrome, with features of rigidity, tremor, and bradykinesia, strength remains relatively intact and corticospinal signs are absent, but effectiveness of movement is nonetheless impaired by the patient's disinclination to use the affected parts (hypo- or akinesia), by slowness (bradykinesia), and by rigidity and tremor. Other clinical syndromes include choreoathetosis, dystonia, and spasms of gaze.

When the parkinsonian syndrome or some component thereof has its onset in middle or late adult life, it usually indicates Parkinson disease or related multisystem forms of striatonigral degeneration. The development of such an extrapyramidal motor disorder in late childhood and adolescence should always suggest Wilson disease, Hallervorden-Spatz disease, and the Segawa type of L-dopa-responsive dystonia.

Hepatolenticular Degeneration (Wilson Disease, Westphal-Strümpell Pseudosclerosis) Wilson's classic description of "progressive lenticular degeneration: a familial nervous disease associated with cirrhosis of the liver" appeared in 1912. A similar neurologic disorder had been described previously by Gowers (1906) under the title of "tetanoid chorea" and by Westphal (1883) and Strümpell (1898), as "pseudosclerosis." None of these authors, however, recognized the association with cirrhosis. The clinical studies of Hall (1921) and the histopathologic studies of Spielmeyer (1920), who re-examined sections from the liver and brain of Westphal's and Strümpell's cases, clearly established that the pseudosclerosis described by these authors was the same disease as the one that had been described by [Wilson](#). Interestingly, none of these authors, including Wilson, noticed the golden-brown (Kayser-Fleischer) corneal ring, the one pathognomonic sign of the disease. The corneal abnormality was first described by Kayser in 1902, and in the following year Fleischer related it to pseudosclerosis. Rumpell had demonstrated the greatly increased copper content of the liver and brain as early as 1913, but this discovery was generally ignored until Mandelbrote (1948) found, quite by chance, that the urinary excretion of copper was greatly increased in patients with Wilson disease, and that it was increased even more after the intramuscular administration of the chelating agent British antilewisite (BAL). In 1952, Scheinberg and Gitlin discovered that ceruloplasmin, the serum protein that binds copper, is consistently reduced in this disease (see reviews by [Scheinberg and Sternlieb](#) for a full historical account and references).

The prevalence of the disease cannot be stated exactly but is on the order of 1 per 50,000 to 1 per 100,000 of the general population. Siblings of a patient with Wilson disease have a 1 in 4 risk of developing the disease. The disease is transmitted as an autosomal recessive trait, and the abnormal gene has been assigned, by linkage analysis, to chromosome 13, in the region 13q14. One of the curious aspects of the genetics of the disease is the multitude of mutations that give rise to the disease within this particular segment of the gene, akin to an allelic variant at a normal site; no one mutation accounts for more than 30 percent of cases. The gene, called ATP7B (homologous with the ATP7A gene, which is defective in Menkes disease), codes for a membrane-bound, copper-binding ATPase. Inadequate functioning of this enzyme in some way reduces excretion of copper in the bile. As noted further on, liver transplantation halts progression of the disease, indicating that the primary effect of the mutation is on the liver rather than the nervous system.

The genetic defect gives rise to two fundamental disturbances of copper metabolism—a reduced rate of incorporation of copper into ceruloplasmin and a reduction in biliary excretion of copper. The deposition of copper in tissues is the cause of virtually all the manifestations of the disease—cirrhosis, hemolytic anemia, degeneration of the basal ganglia, and Kayser-Fleischer rings—as discussed below.

Clinical Features The onset of neurologic symptoms is usually in the second and less often in the third decade, rarely beyond that time. Half of patients are symptomatic by age 15. Exceptional cases, including two with which we are familiar, had their first clinical manifestations as late as their mid-fifties. In all instances, the initial event is a deposition of copper in the liver, leading to an acute or chronic hepatopathy and eventually to multilobular cirrhosis and splenomegaly ([Scheinberg and Sternlieb](#)). In childhood, the liver disorder often takes the form of attacks of jaundice, unexplained hepatosplenomegaly, or hypersplenism with thrombocytopenia and bleeding. The hepatitis may be symptomatic (except for elevated serum transaminases), in which case the initial clinical presentation is neurologic. In some instances, a hemolytic anemia may first draw attention to the disease.

The first neurologic manifestations are almost invariably extrapyramidal and with a proclivity to affect the oropharyngeal musculature. The typical presentations are tremor of a limb or of the head and generalized slowness of movement (i.e., a parkinsonian syndrome); or slowness of movement of the tongue, lips, pharynx, larynx, and jaws, resulting in dysarthria, dysphagia, and hoarseness; or there may be slowness of finger movement and occasionally choreic movements or dystonic postures of the limbs. Often the mouth is held slightly open in the early stage of the disease. Exceptionally, an abnormality of behavior (argumentativeness, impulsiveness, excessive emotionality) or a gradual impairment of intellectual faculties precedes other neurologic signs ([Starosta-Rubinstein et al](#)). As the disease progresses, the

“classic syndrome” evolves: dysphagia and drooling, rigidity and slowness of movements of the limbs; flexed postures; fixity of facial muscles with mouth constantly agape, giving an appearance of grinning or a “vacuous smile”; virtual anarthria (bulbar extrapyramidal syndrome); and a tremor in repose that increases when the limbs are outstretched (coarse, “wing-beating” tremor). Slowed saccadic eye movements and limitation of upgaze are also characteristic. Usually elements of cerebellar ataxia and intention tremor of variable degree are added at some stage of the disease. *A notable feature is the tendency for the motor disorders to be concentrated in the bulbar musculature* and to spread caudally. Thus, the syndrome differs from classic parkinsonism. Approximately 6 percent of patients develop seizures ([Denning et al](#)).

With progression of the neurologic disease, the *Kayser-Fleischer rings* become more evident ([Fig. 37-7](#)). They take the form of a crescentic rusty-brown discoloration of the deepest layer of the cornea (Descemet's membrane). In the purely hepatic stage of the disease, the rings may not be evident (in 25 percent of cases), but *they are invariably present once the neurologic signs become manifest*. A slit-lamp examination may be necessary for their detection, particularly in brown-eyed patients, but in the majority of patients with neurologic signs the rings can be visualized with the naked eye or with the aid of an indirect ophthalmoscope focused on the limbus. Gradually the disability increases because of increasing rigidity and tremor. The patient becomes mute, immobile, extremely rigid, dystonic, and slowed mentally (late and variable effect).

Figure 37-7 Kayser-Fleischer corneal ring (arrow) in Wilson disease. (From [Lyon et al](#) by permission.)

The diagnosis is virtually certain when there is a similar syndrome in a sibling or when an extrapyramidal motor disorder of this type is conjoined with liver disease and the corneal rings. Variants of the above syndrome that the authors have seen are an early choreoathetosis (like Sydenham chorea); prominent dystonic postures; a cerebellar ataxia with minimal rigidity; a syndrome of coarse action or action and intention tremor resembling that of dentatorubral degeneration; an immobile mute state with profound rigidity; and, a dementia, character change, or psychosis with relatively few extrapyramidal signs. Action myoclonus as a prominent early manifestation has also been described.

Laboratory Findings In both the typical and variant forms of the disease, the finding of a low serum ceruloplasmin level (less than 20 mg/dL in 80 to 90 percent of patients), low serum copper (3 to 10 $\mu\text{M/L}$; normal 11 to 24 $\mu\text{M/L}$), and increased urinary copper excretion (more than 100 mg Cu/24 h) corroborate the diagnosis. Because 90 percent of copper is carried by ceruloplasmin, and the latter is generally reduced in Wilson disease, serum copper values alone may be misleadingly normal or low. Early in the course of the illness, the most reliable diagnostic findings are a high copper content in a biopsy of liver tissue (more than 200 mg Cu/g dry weight) and a failure to incorporate labeled ^{64}Cu into ceruloplasmin. The latter test, however, fails to dependably differentiate asymptomatic carriers from affected individuals. Measurement of increased cupriuresis after the administration of pencillamine has not been shown to be more sensitive than an unenhanced 24-h urine collection for copper. Persistent aminoaciduria, reflecting a renal tubular abnormality, is present in most but not all patients. Liver function tests are usually abnormal; some patients are jaundiced and other signs of liver failure may appear late in the illness. In these patients, the serum ammonia may be elevated and the symptomatology may worsen with increases in dietary protein. The cirrhosis may not always be evident in a liver biopsy (some regenerative nodules are large, and the biopsy may be taken from one of them). As mentioned earlier, the large number of mutations that give rise to the disease makes it impractical to use genetic analysis for diagnosis, but once the gene abnormality has been established in a given family, linkage studies may be used to identify other affected sibs.

In studies of large groups of patients, it has been established that copper deposition in the liver is the initial disturbance; over time it leads to cirrhosis. The hepatic stage of the disease precedes neurologic involvement. Cranial CT scans are abnormal even in the hepatic stage, and are invariably so when the neurologic disorder supervenes. The lateral ventricles and often the third ventricle are slightly enlarged, the cerebral and cerebellar sulci are widened, the brainstem appears shrunken, and the posterior parts of the lenticular nuclei, red nuclei, and dentate nuclei become hypodense ([Ropper et al](#)). With treatment, these radiologic changes become less marked ([Williams and Walshe](#)). Magnetic resonance imaging is an even more sensitive means of visualizing the structural changes, particularly those in the subcortical white matter, midbrain, pons, and cerebellum ([Starosta-Rubinstein et al](#)). In the MRI survey by [Saatci and colleagues](#), the putamen was involved most frequently (though not invariably), showing a symmetrical T2 signal change in a laminar pattern; there was also an increase in T1 signal throughout the basal ganglia, particularly in the pallidum. Signal changes are almost universally found in the claustrum and also in the midbrain (pars compacta of the substantia nigra), dentate nucleus of the cerebellum, pons, and thalami. We have been impressed with a glassy diffuse and confluent signal abnormality on T2-weighted and FLAIR images in the hemispherical white matter in some cases—findings that were mistaken for multiple sclerosis.

Neuropathologic Changes These vary with the rate of progress of the disease. Exceptionally, in the rapidly advancing and fatal form, there is frank cavitation in the lenticular (putaminal and pallidal) nuclei, as observed in Wilson's original cases. In the more chronic form there is only shrinkage and a light-brown discoloration of these structures. Nerve cell loss and some degree of degeneration of myelinated fibers in lenticular nuclei, substantia nigra, and dentate nuclei are usually apparent. Subcortical myelin degeneration is found in some cases. More striking, however, is a marked hyperplasia of protoplasmic astrocytes (Alzheimer type II cells) in the cerebral cortex, basal ganglia, brainstem nuclei, and cerebellum.

Treatment Ideally treatment should be started before the appearance of neurologic signs; if this can be effected, the neurologic abnormalities can be prevented to a large extent. Treatment consists of (1) reduction of dietary copper to less than 1 mg/day, which can usually be accomplished by avoidance of copper-rich foods (liver, mushrooms, cocoa, chocolate, nuts, and shellfish), and (2) administration of the copper chelating agent D-penicillamine (1 to 3 g/day) by mouth, in divided doses. Pyridoxine 25 mg/day should be added in order to prevent anemia. The use of D-penicillamine is associated with a number of problems. Sensitivity reactions to the drug (rash, arthralgia, fever, leukopenia) develop in 20 percent of patients and require a temporary reduction of dosage or a course of prednisone to bring them under control. Reinstitution of drug therapy should then be undertaken, using low dosages (250 mg daily) and, later, small, widely spaced increases. If the patient is still sensitive to D-penicillamine or if severe reactions (lupus-like or nephrotic syndromes) occur, the drug should be discontinued and another chelating agent, triethylene tetramine (trientene) or ammonium tetrathiomolybdate, substituted. Zinc, which blocks the intestinal absorption of copper, is also a suitable substitute. It is given as zinc acetate, 100 to 150 mg daily in three to four divided doses at least 1 h before meals ([Hoogenraad et al](#)). The appropriate drug must then be continued for the patient's lifetime. Some women report improvement in neurologic symptoms during pregnancy, although there is no apparent change in copper metabolism during this time. In most patients, neurologic signs improve in response to decoppering agents. The Kayser-Fleischer rings disappear and liver function tests may return to normal, although the abnormalities of copper metabolism remain unchanged. In moderately severe and advanced cases, clinical improvement may not begin for several weeks or months despite full doses of D-penicillamine, and it is important to resist discontinuing the drug during this latent period. One of our patients had a complete remission of neurologic symptoms with penicillamine treatment and has remained symptom-free for 30 years.

It is also well known that the institution of treatment with penicillamine may induce an abrupt worsening of neurologic signs, and we have witnessed several such instances, including one that culminated fatally. Furthermore, in many of these patients, the lost function is never retrieved. Presumably this deterioration is due to the rapid mobilization of copper from the liver and its redistribution to the brain. The slow introduction of penicillamine may avoid this complication. The use of zinc or one of the newer agents mentioned above should be instituted as soon as neurologic deterioration becomes evident. In at least one reported case, new lesions of Wilson disease (shown by MRI) developed while the patient was receiving full doses of D-penicillamine and excellent decoppering of the liver had occurred ([Brewer et al](#)). In the few patients who develop epilepsy, the seizures become apparent soon after therapy is begun.

Many wilsonian patients with advanced liver disease have been subjected to liver transplantation, which is curative for the underlying metabolic defect. The degree of neurologic improvement varies; in some it has been remarkable and sustained, confirming that the hepatic defect is primary and that the brain is involved secondarily. According to Schilsky and coworkers, the main indication for transplantation is severe and progressive liver damage, but the operation has been used successfully in

some patients with intractable neurologic deterioration and only mild signs of liver disease.

An important aspect of treatment is the screening of potentially affected relatives for abnormalities of serum copper and ceruloplasmin; if any relative is found to have the disease, penicillamine should be given indefinitely to prevent the emergence of neurologic symptoms. A full explanation of the dangers of ceasing the medication must be given, and compliance may need to be monitored.

Hereditary Deficiency of Ceruloplasmin This is a rare illness, quite similar to Wilson disease, occurring in patients with a recessively inherited deficiency of ceruloplasmin that is not simply a heterozygous form of Wilson disease (the mutation involves a different gene). Cirrhosis and Kayser-Fleischer rings are not features of the disease, but diabetes is common and extrapyramidal signs may or may not arise. Rather than copper, iron is deposited in the brain and liver (see discussion by [Logan](#)).

Hallervorden-Spatz Disease This disease is also known as *pigmentary degeneration of the globus pallidus, substantia nigra, and red nucleus*. It is inherited as an autosomal recessive trait. The onset is in late childhood or early adolescence, and it progresses slowly over a period of 10 or more years. The early signs are highly variable but are predominantly motor, both corticospinal (spasticity, hyperreflexia, Babinski signs) and extrapyramidal (rigidity, dystonia, and choreoathetosis). General deterioration of intellect is conjoined. In individual cases, ataxia and myoclonus have appeared at some phase of the illness. The spasticity and rigidity are most prominent in the legs, but in some instances they begin in the bulbar muscles, interfering with speech and swallowing, as happens in Wilson disease. We have observed patients who, over a period of years, exhibited only dystonia of the tongue or blepharospasm or arching of the back. The relationship of this restricted form to the complete syndrome remains unsettled. Eventually, the patient becomes almost completely inarticulate and unable to walk or use his arms. Optic atrophy has been mentioned in a few reports, but we have not observed it.

No known biochemical test corroborates the diagnosis. The characteristic deposits of iron in the basal ganglia have not been associated with a demonstrable abnormality of serum iron or of iron metabolism. It has, however, been reported that there is a high uptake of radioactive iron in the region of the basal ganglia following intravenous injection of labeled ferrous citrate ([Vakili et al](#), [Szanto and Gallyas](#)). This technique may prove to be useful in diagnosis. CT scanning reveals hypodense zones in the lenticular nuclei, resembling those of hepatolenticular degeneration, sulfite oxidase deficiency, glutaric acidemia, and Leigh disease, although high-density lesions have been described in one autopsy-proven case of this disease ([Tennison et al](#)). The MRI findings are striking ([Fig. 37-8](#)). In T2-weighted images, the pallidum appears intensely black, with a small white area in its medial part ("eye of the tiger" sign; see also [Savoiaro et al](#)).

Figure 37-8 Hallervorden-Spatz disease. T2-weighted MR image showing areas of decreased signal intensity of the pallidum bilaterally (corresponding to iron deposition) and a central high signal area due to necrosis ("eye of the tiger" sign).

The neuropathology proves to be the most distinctive attribute of the disease. There is an intense brown pigmentation of the globus pallidus, substantia nigra (especially the anteromedial parts), and red nucleus. Granules and larger amorphous deposits of iron mixed with calcium stud the walls of small blood vessels or lie free in the tissue. A loss of neurons and medullated fibers occurs in the most affected regions. Another unique feature is the presence of swollen axon fragments, which resemble those of neuroaxonal dystrophy; for this reason, some neuropathologists regard Hallervorden-Spatz disease as a juvenile form of neuroaxonal dystrophy. Iron deposits are less conspicuous in the latter disease, leaving this interpretation in doubt. The significance of iron deposition is difficult to judge. To some extent, there is an increase of iron in the basal ganglia in other degenerative diseases. In Parkinson disease and striatonigral degeneration, for example, the deposition of iron is two to three times normal, presumably the result of degeneration of those tissues that are known to be rich in iron.

No treatment is known to be effective. Some of our patients responded temporarily to L-dopa, but the effect was slight. The use of chelating agents to reduce iron storage has not helped.

Differential Diagnosis of Wilson and Hallervorden-Spatz Diseases Disorders that must be differentiated from Wilson and Hallervorden-Spatz diseases are tardive dyskinesia, restricted forms of dystonia, adult and juvenile Parkinson disease and the related Segawa type of L-dopa-responsive dystonia, early-onset rigid form of Huntington chorea, status dysmyelinatus, Fahr disease (see below), Lafora-body disease, Leigh subacute necrotizing encephalomyelopathy, multiple sclerosis, dentatorubropallidoluysian degeneration, ceroid lipofuscinosis, polyglucosan disease, and other rare, presumably biochemical disorders of unknown type. Several of these have come to our attention, simulating at least some components of the extrapyramidal picture of Wilson disease but without evidence of liver involvement or copper abnormality. Difficult to categorize are diseases such as the one reported by [Willvonseder and colleagues](#)—in which a mild dementia, spastic dysarthria, paresis of vertical eye movements, gait disturbance, and splenomegaly came on during early adult life. Here abnormalities of copper metabolism were found (slightly decreased serum ceruloplasmin, copper turnover values in the range of those in heterozygous carriers of Wilson disease, but no increase in urinary copper excretion). The authors have seen several such patients. One such individual in her fifties with the subacute onset of parkinsonism, severe dysarthria, wilsonian facies, mild ataxia, and exaggerated facial and limb reflexes had symmetrical signal changes in the pallidum and dentate nucleus and diffusely through the white matter. She had some degree of improvement without treatment.

In families known to have Huntington chorea, children and some adults may be afflicted with a predominantly rigid-parkinsonian form (Westphal variant). About 5 percent of all cases of Huntington chorea are of this "juvenile type." Rather than a movement disorder, this condition is marked by a slow decay in intellect, slurred speech, rigidity of the limbs, short-stepped gait, and flexion hypertonia of the limbs and trunk. Nevertheless, choreoathetosis does eventually appear in some cases. Ocular movements are full except for upward gaze. The disease is inexorably progressive, and eventually the patient becomes mute and rigidly immobile, with mouth agape, limbs flexed, and hands fisted in fixed, dystonic postures. Progressive supranuclear palsy may for a considerable period of time lack the characteristic limitation of vertical gaze, or it may be minimal. The main features are then axial rigidity, extension dystonia of the neck, and some rigidity and dystonia of the limbs. This differentiation has presented problems in diagnosis in a few of our patients whose illness began in their late forties or fifties. See [Chap. 39](#) for discussion of the neuropathology and treatment of these two diseases.

Juvenile paralysis agitans was described by Ramsay Hunt in 1917. Judging by the descriptions, the resemblance to adult Parkinson disease is close. The course is slowly progressive. A familial incidence (two brothers aged 10 and 19) was reported by [van Bogaert](#), but most cases have been sporadic. Postmortem examination has reportedly shown a shrinkage of the lenticular nuclei and a loss of large cells in the pallidum, but in an anatomic specimen from van Bogaert's laboratory (the age of onset was 7 years), cell loss was noted in the substantia nigra and pallidum. There was no evidence of encephalitis lethargica, and the pathologic findings differed from those of paralysis agitans, Wilson disease, Hallervorden-Spatz disease, and Huntington chorea. The authors are puzzled about this entity and have had no personal experience with it upon which to base an opinion. It may be linked with the early-onset type of parkinsonism-dystonia that is responsive to L-dopa.

The status dysmyelinatus of Vogt and Vogt represents another obscure disease in which all myelinated fibers and nerve cells in the lenticular nuclei (both striatofugal and pallidofugal) disappear. The principal clinical features are extrapyramidal rigidity and, later, athetosis. Eventually the child becomes helpless, with limbs in weird postures and contorted by spasms. At one stage it is said to resemble Parkinson disease.

In isolated late-life cases of Lafora-body disease (discussed earlier in this chapter), there may be rigidity, akinesia, and tremor; but usually myoclonus, seizures, and dementia dominate the picture. Rarely, Leigh disease (described later in the chapter) gives rise to a slowly evolving extrapyramidal rigidity in late childhood or

adolescence with bilateral cavitation of the putamen in CT scans.

The differential diagnosis of the aforementioned diseases presents certain difficulties. The recognition of Hallervorden-Spatz disease was for many years a problem for want of a satisfactory laboratory test, but this has been simplified by MRI, as noted above. The similarities between the diseases included under the rubric of the Parkinson syndrome are in general smaller than the differences. Wilson disease, for example, shares certain signs with Parkinson disease, yet the appearance of each is in general distinctive. The special qualities of the facial expression in Wilson disease—as well as the dysarthria, severe ataxic tremor, rigidity, and dystonia—are not readily confused with Parkinson disease. Furthermore, in several of the diseases in this category, there may be myoclonus and extrapyramidal signs such as choreoathetosis, dystonia, and so on, which are essential parts of the next category of syndromes. Therefore one must not insist that each disease conform strictly to a unique clinical syndrome.

The Syndrome of Dystonia and Generalized Chorea and Athetosis

As indicated in [Chap. 4](#), we do not find the differences between dystonia and choreoathetosis to be fundamental. If one examines many patients with these involuntary movements, every gradation between the two is seen; not infrequently, the quicker, unpatterned involuntary movements of chorea and ballismus are seen as well. Even tremor and myoclonus may complicate the composite movement disorder. With reference to muscular tone in patients with athetosis and dystonia, there are unpredictable associations of hypertonia and hypotonia.

A number of inherited metabolic diseases, all of them rare, express themselves by the syndrome of chorea, athetosis, and dystonia.

The Lesch-Nyhan Syndrome and Hyperuricemia This rare metabolic disease is inherited as an X-linked recessive trait. Although it carries the names of Lesch and Nyhan (1964), the occurrence of uricemia in association with spasticity and choreoathetosis in early childhood had been described earlier by Catel and Schmidt. Essentially it is a hereditary choreoathetosis with self-mutilation and hyperuricemia. The affected children appear normal at birth and usually develop on schedule up to 3 to 6 months of age. Maturation delay then sets in, initially with hypotonia that later gives way to hypertonia. Also, the patients' behavior becomes abnormal, with aggressiveness and compulsive actions. The compulsive self-mutilation, mainly of the lips, occurs early (during the second and third year), and spasticity, choreoathetosis, and tremor come later. Most of the children learn to walk. Speech is delayed and, once attained, it is dysarthric throughout life. Mental retardation is moderately severe. In patients more than 10 years of age, gouty tophi appear on the ears, and there is increasing risk from gouty nephropathy. The serum levels of uric acid are in the range of 7 to 10 mg/dL.

A deficiency of the enzyme hypoxanthine-guanine-phosphoribosyl transferase (HPRT) has been found in all typical cases of this disease. The HPRT gene lies on the X chromosome (Xq 26-q 27), and accurate diagnosis of affected males and carriers can be made by DNA analysis. As a result of this deficiency, hypoxanthine is either excreted or catabolized to xanthine and uric acid. The details of the biochemical abnormality responsible for CNS dysfunction are unclear.

In the differential diagnosis, one must consider nonspecific mental retardation with hand biting and other self-mutilations, athetosis from birth trauma, and encephalopathies with chronic renal disease. Hyperuricemia has also been reported in a family with spinocerebellar ataxia and deafness and in another with autism and mental retardation, neither of them with the enzymatic defect of Lesch-Nyhan disease. As mentioned earlier, there are several other disorders of purine and pyrimidine metabolism, some of them with hyperuricemia, that present with a neurologic syndrome like that of Lesch-Nyhan.

Treatment with the xanthine oxidase inhibitor allopurinol, which blocks the last steps of uric acid synthesis, reduces the uric acid in Lesch-Nyhan disease and prevents the uricosuric nephropathy, but it seems to have no effect on CNS symptoms. Guanosine 5-monophosphate and inosine 5-monophosphate, both of which are deficient in Lesch-Nyhan disease, have been replaced without benefit to the patient. Transitory success has been reported with the administration of 5-hydroxytryptophan in combination with L-dopa. Fluphenazine (Prolixin) is reported to have eliminated the self-mutilation after haloperidol (Haldol) had failed to do so. Behavior modification programs may be of some value.

Calcification of Vessels in Basal Ganglia and Cerebellum (Hypoparathyroidism and Fahr Syndrome) Ferruginization and calcification of vessels in the basal ganglia occur to a slight degree in many elderly persons (and in other mammals) who are otherwise normal. The widespread use of CT scans and MRI has brought the condition to light with increasing frequency ([Fig. 37-9](#)). Usually it may be dismissed as an aging phenomenon of no clinical significance. When it occurs early in life and is of such degree as to be visible in plain films of the skull, it must always be regarded as abnormal. An adult case of this type was described by [Fahr](#), so that his name is sometimes attached to this disorder, but it was known long before his publication appeared, and his account added little to our knowledge of the condition.

Figure 37-9 Above: Idiopathic basal ganglionic calcification in a 25-year-old woman without symptoms or signs of cerebral disease. Below: Idiopathic basal ganglionic and cerebellar calcification, discovered 5 years after the onset of a slowly progressive rigid Parkinson syndrome in a 54-year-old woman.

Many authors have called attention to a form of calcification of the basal ganglia and cerebellum in which choreoathetosis and rigidity are prominent. The clinical state may also take the form of a parkinsonian syndrome or bilateral athetosis. In several of our patients there was a unilateral choreoathetosis, which was replaced gradually by a parkinsonian syndrome. In two of our sporadic cases, the initial abnormality was a unilateral dystonia, responsive to L-dopa. Some patients have been mentally retarded, others intellectually intact. We have observed a familial form of basal ganglionic–cerebellar calcification inherited as an autosomal recessive trait. Its onset was in adolescence and early adult life and it presented clinically as a complex syndrome of choreoathetosis, tremor, ataxia, and dementia. The serum calcium levels in the aforementioned types of cases are usually normal, and there is no explanation of the calcification. This was also true of our cases. In a family described by [Martinelli and colleagues](#), there was autosomal dominant inheritance and abnormal vitamin D metabolism.

In hypoparathyroidism (idiopathic or acquired) and pseudohypoparathyroidism (a rare familial disease characterized by the symptoms and signs of hypoparathyroidism in association with distinctive skeletal and developmental abnormalities), the diminution in ionized serum calcium induces not only tetany and seizures but sometimes choreoathetosis as well. This last symptom is presumably due to calcification of the basal ganglia, which occurs in about one-half of the patients. Also, in some instances there are signs of a cerebellar lesion.

Sly and colleagues have described the familial occurrence (21 cases in 12 families) of calcification in the caudate and lenticular nuclei, thalami, and frontal lobe white matter in association with osteopetrosis (“marble bones”) and renal tubular acidosis. Clinically there were multiple cranial nerve palsies—including optic atrophy as well as psychomotor delay and learning disabilities—but no extrapyramidal signs. The cranial nerve palsies, which are due to bony encroachment in neural foramina, were much less severe than in the lethal form of osteopetrosis. The pattern of inheritance of this disease is autosomal recessive, and the basic abnormality was found to be a deficiency in carbonic anhydrase II in red blood corpuscles and probably in kidney and brain.

Other Metabolic Disorders Associated with Choreoathetosis and Dystonia Exceptionally, ceroid-lipofuscinosis of the Kufs type, G_{M1} gangliosidosis, late-onset metachromatic leukodystrophy, Niemann-Pick disease (type C), Hallervorden-Spatz disease, and Wilson disease may present with a syndrome of which dystonia or athetosis is an important component. Usually, other elements in the clinical picture are detectable, so that the correct diagnosis is seldom in doubt for long. Dal Canto and colleagues have described a variant of *neuronal ceroid-lipofuscinosis* in which a boy and girl of unrelated non-Jewish parents developed severe choreoathetosis and dystonia at 6 to 7 years of age. Intellectual deterioration, gait abnormality, and seizures were the other clinical features. Cerebral biopsy showed intraneuronal

inclusions consisting of curvilinear bodies. These observations support the notion of nosologic heterogeneity among the nonglycolipid neuronal storage disorders.

Glutaric acidemia (type I) is another rare metabolic disorder, in which progressive choreoathetosis and dystonia are added to an intermittent acidemia. In some cases, ataxia of movement and a variable degree of mental retardation are also present. Glutaric acid is present in the urine, as are its metabolites 3-OH glutarate and glutamate. The basic defect is in glutaryl CoA dehydrogenase, which has been found in leukocytes, hepatocytes, and fibroblasts. Neuropathologically, there is loss of neurons in the caudate, putamen, and pallidum, with gliosis. A spongy change is said to affect the white matter.

Infants with glutaric acidemia often present with sudden episodes of acidosis, coma, and flaccidity, associated with a signal change on MRI, corresponding to the acute necrosis of nerve cells in the basal ganglia. These crises can be prevented and the infants can develop normally if the diagnosis is made before the development of neurologic signs (as in a sibling of an older affected child) and treatment is undertaken with a diet low in protein, particularly in tryptophan and lysine ([Cho et al](#)).

Finally, in regard to extrapyramidal motor disorders, it should be pointed out that those of acquired type are much more common than inherited ones. A prototype of athetosis is known to follow hypoxic encephalopathy of birth, leading to *état marbré* of the basal ganglia. This is the basis of the double athetosis syndrome that usually becomes manifest only after the first year of life and persists thereafter (page 1085). The Rh and ABO blood incompatibilities that induce erythroblastosis fetalis and *kernicterus* may also be the cause of a bilateral athetosis at about the same period of life, but this syndrome is distinguished by deafness and paralysis of upward gaze (page 1085). The same is true of the Crigler-Najjar form of hereditary hyperbilirubinemia, in which kernicterus (with ataxia or athetosis) may rarely appear as late as childhood or adolescence; the defect is one of glucuronide-bilirubin conjugation.

A number of other rare diseases, which can only be classified as hereditary degenerations, must also figure in the differential diagnosis of choreoathetotic or dystonic syndromes. Torsion dystonia is the best-known example (page 1141). One familial variant with certain features of Parkinson disease and responsive to L-dopa (Segawa disease) is described in [Chap. 39](#). A nonprogressive familial choreoathetosis with onset in early childhood has been reported by [Pincus and Chutorian](#); here, cerebellar signs were usually conjoined but the intellect was spared. This syndrome is thought to be inherited as an autosomal recessive trait. We have also encountered families with an uncomplicated choreoathetosis, which is inherited as an autosomal dominant trait. A paroxysmal and sometimes kinesogenic form of *familial choreoathetosis* was recognized by [Mount and Reback in 1940](#) and subsequently elaborated by [Lance](#) (page 83). One wonders in retrospect if some of these patients were dopamine-responsive. We have observed attacks of this kind in children with “cerebral palsy” as a manifestation of phenytoin (or carbamazepine) toxicity; lowering the dose of the drug terminated the attacks.

Sethi and coworkers have described an adult with dementia and choreoathetosis, simulating Huntington chorea, in whom episodic nausea, vomiting, and lethargy during childhood were due to propionic aciduria. The movement disorder did not appear until the patient was 28 years old. In others, the chorea begins in infancy and persists despite treatment. The authors have added this disease to the other inherited choreas (Huntington disease, neuroacanthocytosis, familial calcification of basal ganglia, Hallervorden-Spatz disease, dentatorubrothalamic atrophy).

Several of the above-mentioned diseases are presently classified as degenerative and are discussed in [Chap. 39](#).

Bilateral Hemiplegia, Cerebral Blindness, and Other Manifestations of Decerebration (the Leukodystrophies)

Embodied in this heading are the features that characterize the aforementioned “white matter syndrome” by which most of the familial leukodystrophies are expressed. Of the several varieties of late-onset leukodystrophy, some are of unquestionable metabolic origin and others of uncertain status. As emphasized earlier, all differ from the cerebral gray matter diseases (poliodystrophies), which have a different mode of presentation—seizures, myoclonus, chorea, choreoathetosis, and tremor being prominent. Categorization of the entire group of leukodystrophies is based on the identification of symptoms and signs attributable to the interruption of tracts (corticospinal, corticobulbar, cerebellar peduncular, sensory, medial longitudinal fasciculi) and visual pathways (optic nerve, optic tract, geniculocalcarine), and the infrequency or absence of seizures, myoclonus, and spike-and-wave abnormalities in the EEG. However, this distinction is not always reliable, particularly in the later stages of the disease. The terms *metachromatic*, *sudanophilic*, *orthochromic*, etc., refer to the distinctive products of myelin degeneration and staining characteristics of the white matter in the individual leukodystrophies.

The syndrome of progressive spasticity and rigidity with spastic dysarthria and pseudobulbar palsy poses a difficult diagnostic problem. One's first impulse is to assume the presence of a corticospinal disorder, especially if tendon reflexes are brisk, but frequently the plantar reflexes are flexor and the facial reflexes are not enhanced. The opposite combination of Babinski signs and reduced or absent tendon reflexes, signifying a combination of corticospinal and peripheral nerve lesions, is highly characteristic of metachromatic leukoencephalopathy, adrenomyeloneuropathy, or subacute combined degeneration of the spinal cord (vitamin B₁₂ deficiency). Unusual postures and a more plastic type of rigidity are consistent with an extrapyramidal condition. Such combinations, with mental backwardness and dementia, characterize the mild and late forms of *metachromatic leukodystrophy*—which may be taken as a paradigm of the leukoencephalopathies.

The leukodystrophies that become apparent only in later life pose another problem—the clinical and radiologic differentiation from multiple sclerosis. In cases of early onset, in which myelin has yet to be normally formed, the metabolic disturbance may result in hypomyelination (e.g., Pelizaeus-Merzbacher disease); by contrast, the process in adolescent or adult-onset cases is one of destruction of myelin already formed. In identifying the metabolic diseases, one is helped by the relative symmetry and steady progression of the clinical signs; the early onset of cognitive impairment (which is uncharacteristic of multiple sclerosis); and the symmetrical and massive degeneration of the cerebral white matter (in distinction to the asymmetrical and often multiple lesions of demyelinating disease).

Adrenoleukodystrophy (Sudanophilic Leukodystrophy with Bronzing of Skin and Adrenal Atrophy) This combination of leukodystrophy and Addison disease, originally included under the rubric of Schilder disease, is now set apart as an independent metabolic encephalopathy. It is transmitted as an X-linked recessive trait with an incidence of 1 in 20,000 male births. The fundamental defect is an impairment in peroxisomal oxidation of very long chain fatty acids (VLCFA), leading to their accumulation in the brain and adrenal glands ([Igarashi and associates](#)). The deficient membrane protein is encoded by a gene that maps to chromosome X28, close to the gene for color vision.

The onset is usually between 4 and 8 years, sometimes later; in the commonest form of this disorder, only males are affected (probably sex-linked recessive). The signs of either the adrenal insufficiency or the cerebral lesion may be the first to appear. In the case of Siemerling and Creutzfeldt, the first recorded example of this disorder, bronzing of the skin of the hands appeared at 4 years of age; quadriparesis, with dysarthria and dysphagia (i.e., pseudobulbar palsy), became evident at 7 years; a single seizure occurred at 8 years; and by 9 years, shortly before death, the patient was *decerebrate* and unresponsive. In personally observed cases, the first abnormalities appeared at 9 to 10 years and took the form of episodic vomiting, decline in scholastic performance, and change in personality, with silly, inappropriate giggling and crying. After a time, severe vomiting and even an episode of circulatory collapse occurred, following which the gait became unsteady and arms ataxic, with an action or intention tremor. Only then did increasing pigmentation of the oral mucosa and the skin around nipples and over elbows, knees, and scrotum become evident. *Cortical blindness* followed in some instances. The late stages were marked by bilateral hemiplegia (at first asymmetrical), pseudobulbar paralysis, blindness, deafness, and impairment of all higher cerebral functions. The severity of the disease varies. We are caring for several adult men in whom the cerebral symptoms have been mild, allowing for high-level cognitive function, the main manifestations consisting of personality quirks, spastic gait, urinary difficulty, testicular insufficiency, and baldness. Two of the men related the characteristic history of a male sibling who died in childhood, ostensibly of Addison disease.

Griffin and coworkers have described a spinal-neuropathic form of the disease (adrenomyeloneuropathy). In their patients, evidence of adrenal insufficiency was present since early childhood, but only in the third decade of life did a progressive spastic paraparesis and a relatively mild polyneuropathy develop. The spasticity is occasionally asymmetrical, and the gait may have an ataxic component. This neurologic picture, in mild form and without adrenal insufficiency, is the manner in which the disease may present in female carriers of the gene abnormality.

Moser and colleagues, using clinical and biochemical criteria, have identified the following subtypes: (1) familial instances of Addison disease without neurologic involvement in males, but with a mild spastic paraparesis in females; (2) progressive degeneration of cerebral white matter in young males, often with cortical blindness—the classic type ([Fig. 37-10](#)); (3) an intermediate form in juvenile or young adult males with cerebral and spinal involvement; (4) a progressive spinal cord tract degeneration in adult males; (5) a chronic nonprogressive spastic paraparesis in *heterozygous females*; and (6) possibly, in male infants, a form originating at birth (e.g., Zellweger disease).

Figure 37-10 Adrenal leukodystrophy in a 7-year-old male. A confluent area of increased signal involves the occipital and parietal white matter; there is also asymmetrical involvement of the white matter in the frontal lobes. The lower image demonstrates the changes on a lower cut, including involvement of both the anterior and posterior portions of the corpus callosum (long-stemmed arrows). (From Bisese JH: *Cranial MRI*. New York, McGraw-Hill, 1991, by permission.)

Illustrating the variability in presentation among kindreds, Marsden and colleagues and, subsequently, Kobayashi and colleagues described a familial spinocerebellar syndrome, and Ohno and associates have reported a sporadic instance of adrenoleukodystrophy presenting as olivopontocerebellar atrophy. Moser found cerebral forms alone in 30 percent, adrenomyeloneuropathy alone in 20 percent, and combined childhood cerebral and myelopathic forms in the remaining half. Regarding the heterozygotes, neurologic manifestations have been said to develop in up to 50 percent, but in our experience with siblings of affected patients, the figure has been lower. The onset of a spastic paraparesis tends to occur later, usually in the third or fourth decade, and progression tends to be slow, but an explosive onset has been reported. As already mentioned, multiple sclerosis is the main consideration in differential diagnosis, particularly since 20 percent of heterozygotes have white matter changes on cerebral MRI. Overt adrenal insufficiency is rare in female carriers, but scalp hair may be scant as a subtle manifestation of adrenal dysfunction.

The specific laboratory marker of the disease is an excess of VLCFAs, in particular hexacosanoic acids, in plasma, erythrocytes, leukocytes, or cultured fibroblasts; this reflects the basic biochemical fault in this disease, namely defective fatty acid oxidation within the peroxisomes. If skin fibroblasts and plasma testing are both performed, 93 percent of female carriers will show the abnormal VLCFA. Cranial MRI is abnormal in the majority of patients with cerebral symptoms and in a proportion of others.

Other important laboratory findings are low serum sodium and chloride levels and elevated potassium levels—reflecting the atrophy of the adrenal glands. The latter results in reduced excretion of corticosteroids, low serum cortisol levels, and lack of rise in 17-hydroxyketosteroids after ACTH stimulation. Adrenal insufficiency may be the only manifestation of the disease. The CSF protein may be elevated.

In classic instances, massive degeneration of the myelin occurs, often asymmetrically in various parts of the cerebrum, brainstem, optic nerves, and sometimes spinal cord ([Fig. 37-10](#)). Degradation products of myelin are visible in macrophages in recent lesions—namely, sudanophilic demyelination. Axis cylinders are damaged, but to a lesser degree. The cortex of the adrenal glands is atrophic, and the cells and invading histiocytes contain an abnormal lipid material. The testes show marked interstitial fibrosis and atrophy of the seminiferous tubules. Electron microscopically, the macrophages of the brain and adrenals and the Leydig cells of the testes contain characteristic lamellar cytoplasmic inclusions.

Adrenal replacement therapy prolongs life and occasionally effects a partial neurologic remission. A diet enriched with monounsaturated fatty acids and devoid of long-chain fatty acids appears to slow the progress of the disease in some cases. Bone marrow transplantation, to date performed in over 50 children, has been the only treatment shown to stabilize the disease and reverse some of the MRI changes. The review by [van Geel and colleagues](#), summarizing current diagnosis and treatment, is recommended.

Metachromatic Leukodystrophy (MLD) This form of leukodystrophy has already been described in relation to the inherited metabolic disorders of late infancy and early childhood (page 1012). It is mentioned here again to emphasize the point that the disease may have its onset at almost any age. Juvenile forms may begin between 4 and 12 years and adult forms between the mid teens and the seventh decade. Some of the sporadic cases reported in the adult have probably been examples of cerebral multiple sclerosis, but we have seen, as have others, cases of MLD appearing as late as middle adult life. In all cases, the clinical picture is one of intellectual decline with spastic weakness, hyperreflexia, Babinski signs, and stiff, short-stepped gait. As the disease progresses over a period of 3 to 5 years, there is a loss of vision and speech, then of hearing, and finally a state of virtual decerebration.

In some of these cases it is impossible to distinguish the white matter disease from that of Pelizaeus-Merzbacher and of Cockayne, described in the preceding section.

Cerebrotendinous Xanthomatosis This rare disease is probably transmitted by an autosomal recessive gene. It usually begins in late childhood, with cataracts and xanthomata of tendon sheaths and lungs. As it progresses, difficulty in learning, impairment of retentive memory, and deficits in attention and visuospatial perception (the earliest neurologic manifestations) give way to dementia, ataxic or ataxic-spastic gait, dysarthria and dysphagia, and polyneuropathy. In the late stages (after 5 to 15 years), the patient becomes bedfast and helpless; death occurs at 20 to 30 years of age. In other cases the clinical course is much more benign. Neuropathologic examination shows masses of crystalline cholesterol in the brainstem and cerebellum and sometimes in the spinal cord, with symmetrical destruction of myelin in the same areas. The lesions are visible by CT scanning and MRI.

The basic defect is in the synthesis of primary bile acids, leading to an increased hepatic production of cholesterol and cholestanol, which accumulate in brain and tendons. The serum cholesterol levels are normal in most cases but as high as 450 mg/dL in others. The tendon xanthomas contain cholesterol, of which 4 to 9 percent is cholestanol (dihydrocholesterol). Cholestanol levels in the serum and red cells are increased. The same elevated levels are found in heterozygotes.

In response to long-term treatment with chenodeoxycholic acid, 750 mg daily, the corticospinal and cerebellar signs and dementia receded in 10 of 17 patients followed by [Berginer and coworkers](#). This drug corrects the defective synthesis of bile acids and restores the low level of chenodeoxycholic acid. Ideally treatment should begin before the neurologic symptoms appear ([Meiner et al](#)).

Strokes in Association with Inherited Metabolic Diseases

In [Chap. 34](#) it was remarked that strokes occur from time to time in children and young adults, often due to inherited disorders of the clotting system typified by protein C deficiency, but also due to a number of other metabolic derangements. Among the many causes, three metabolic diseases must always be considered in the diagnosis of such cases: homocystinuria, Fabry disease, and sulfite oxidase deficiency. Other less common ones are Tangier disease and familial hypercholesterolemia. Stroke in young persons is also a central feature of the mitochondrial disorder MELAS, discussed further on in this chapter.

Homocystinuria This aminoaciduria is inherited as an autosomal recessive trait and simulates Marfan disease. Tall, slender habitus, great length of limbs, sometimes scoliosis and arachnodactyly (long, spidery fingers and toes), thin and rather weak muscles, knock-knees, highly arched feet, and kyphosis are the typical skeletal features. Sparse, blond, brittle hair, malar flush, and livedo reticularis are common dermal manifestations, and a dislocation of one or both lenses (usually downward) may occur, imparting a tremulous appearance to the irides (iridodonesis). The only neurologic abnormality is mental retardation, usually of mild degree, which sets this syndrome apart from Marfan disease, in which intellect is unimpaired.

Blood vessel changes—thickening and fibrosis of the coronary, cerebral, and renal arteries—tend to appear later in the illness. An abnormality of platelets favoring clot formation and thrombosis of cerebral arteries has been observed. Some patients have died of coronary occlusions during adolescence, and a myocardial lesion may be the source of emboli to cerebral arteries.

Homocystine is elevated in the blood, CSF, and urine. This is due to an inherited cystathionine synthase deficiency that results in an inadequacy of cystathionine formation, a substance essential to many tissues including the brain. This may be the explanation of the mental retardation. Plasma methionine levels are also elevated. The infarcts in the brain are clearly related to thrombotic and embolic arterial occlusions. The administration of a low-methionine diet and large doses (50 to

500 mg) of pyridoxine (a cystathionine synthase coenzyme) reduces the excretion of homocystine. If vascular lesions have occurred, anticoagulants probably prevent further occlusions.

Homocystinuria may also be an expression of 5,10-methylenetetrahydrofolate reductase deficiency. Again, the clinical manifestations consist of multiple cerebrovascular lesions, dementia, epilepsy, and polyneuropathy. The last is believed to be due to a coincidental folic acid deficiency, but in some cases it may have been caused by chronic phenytoin administration ([Nishimura et al](#)).

Fabry Disease (Anderson-Fabry Disease, Hereditary Dystopic Lipidosis) This disease, also known as *angiokeratoma corporis diffusum*, is inherited as an X-linked recessive trait. It occurs in complete form in men and in incomplete form in female carriers. The primary deficit is in the enzyme α -galactosidase A, the result of which is the accumulation of ceramide trihexoside in endothelial, perithelial, and smooth muscle cells of the blood vessels as well as in renal tubular and glomerular cells and other viscera and in nerve cells in many parts of the nervous system (hypothalamic and amygdaloid nuclei, substantia nigra, reticular and other nuclei of the brainstem, anterior and intermediolateral horns of the spinal cord, sympathetic and dorsal root ganglia). The disease becomes manifest clinically in childhood or adolescence, with intermittent lancinating pains and dysesthesias of the extremities. A notable feature of these pains is their evocation by fever, hot weather, and vigorous exercise. Usually there is no sensory loss, but autonomic disturbances have been recorded in a series of our cases. Later, the diffuse vascular involvement leads to hypertension, renal damage, cardiomegaly, and myocardial ischemia. Thrombotic infarctions occur in the brain during early adult years. The characteristic angiokeratomas tend to be most prominent periumbilically and resemble small angiomas that obliterate slightly with pressure. Enzyme replacement is now available. Desnick and colleagues have reviewed the neurologic, neuropathologic, and biochemical findings in this disease. Its painful neuropathic features are discussed on page 1422.

Sulfite Oxidase Deficiency This disorder was discussed briefly with the neonatal metabolic disorders (page 933). The occurrence of stroke as a complication of this disorder was placed on record by [Shih and colleagues](#). A child 4.5 years of age, whose development had been retarded since birth (seizures and opisthotonos had been present), became hemiplegic. Another unrelated child, supposedly normal until 2 years of age, entered the hospital with fever, confusion, generalized seizures, right hemiplegia, and aphasia (infantile hemiplegia); subluxation of the lenses (upward) was discovered later. There was an increased level of sulfite and thiosulfite and an abnormal amino acid, S-sulfocysteine, in the blood. One child appeared to respond to a low-sulfur–amino acid diet.

Changes in Behavior and Intellect as Manifestations of Inherited Metabolic Disease

Although rare among the large numbers of maladjusted, sociopathic, and psychotic adolescents, certain metabolic diseases may cause serious disturbances of mental life and behavior. The diagnosis and management of these metabolic diseases are so special that some special remarks are appropriate.

All the metabolic diseases of late childhood and adolescence may share to some degree the property of deranging behavior, thinking, feeling, and emotional reactions. The most obvious and easily detectable of these derangements are in the cognitive sphere, i.e., reduction in the capacity to learn and remember, to calculate, to solve problems, and to exercise verbal skills. Impulsivity, loss of self-control, and antisocial behavior are the most troubling behavioral abnormalities. Certain forms of these impairments are attributable to integrated systems of modules of cerebral neurons and are recognized as special neurologic deficits, such as the amnesic state, aphasia, dyscalculia, and visual-perceptual disorientation. Each of these phenomena has its own cerebral anatomy, as pointed out in [Chap. 22](#), and the state known as dementia comprises various degrees and combinations of these abnormalities.

Intellectual functions are little developed in early childhood; it is therefore difficult to decide upon normal qualities of the mind for this age group. Slowness in learning, in acquiring language functions, and so on may be interpreted loosely as mental retardation. At this age these intellectual functions have not developed sufficiently to permit recognition of their regression. Only in late childhood do mental retardation and dementia become clearly distinguishable. Far less tangible are subtle changes in personality and behavior that must always be judged against the standards of the cultural group of which the patient is a member.

The principle that most neuropsychiatrists follow in selecting from the large mass of maladjusted adolescents those with a metabolic brain disease is that such a condition will sooner or later cause a *regression in cognitive and intellectual functions*. Schizophrenia and manic-depressive psychosis and the sociopathies and character disorders do so little or not at all. This is not to say that personality changes and emotional disturbances do not occur in the metabolic encephalopathies; of course they do. However, their recognition depends more on the demonstration of failing memory, impaired thinking, inability to learn, and loss of verbal and arithmetic abilities, many of which are measured quantitatively by intelligence tests.

If one reviews all the diseases described in this chapter and selects those that may demonstrate *early regression of cognitive function in association with personality change and alteration of behavior*—diseases that may for a time be unaccompanied by other neurologic abnormalities—the following merit special consideration:

1. Wilson disease
2. Hallervorden-Spatz pigmentary degeneration
3. Lafora-body myoclonic epilepsy
4. Late-onset neuronal ceroid-lipofuscinosis (Kufs form)
5. Juvenile and adult Gaucher disease (type III)
6. Some of the mucopolysaccharidoses
7. Adrenoleukodystrophy
8. Metachromatic leukodystrophy
9. Adult G_{M2} gangliosidosis
10. Mucopolipidosis I (type I sialidosis)
11. Nonwilsonian copper disorder (hereditary ceruloplasmin deficiency)

In each of the above diseases, dementia and personality disorder may gradually develop and persist for many months, even a year or two, before other neurologic signs appear. One must look carefully for the earliest signs of movement disorders and other neurologic abnormalities, which greatly clarify the diagnostic problem. A safe rule is to assume that if there are mental and personality changes in each of the above diseases, other subtle neurologic disorders coexist. The common use of neuroleptic drugs, causing tardive dyskinesia, is the major obstacle to applying this rule.

ADULT FORMS OF INHERITED METABOLIC DISEASES

The increasing range and precision of biochemical and cytologic tests has brought to light a number of inherited metabolic diseases that sometimes have their onset in adult life. Such disorders, while uncommon, nevertheless are important because they must be considered in the differential diagnosis of degenerative diseases and atrophies, for which explanations are beginning to be found. Also to be considered in the differential diagnosis is an array of mitochondrial disorders, to be discussed further on in this chapter.

In the last decade or two, the authors have personally observed or have otherwise come to know of examples of the following metabolic diseases, the onset of which was in late adolescence or adult life:

1. Metachromatic leukoencephalopathy
2. Adrenoleukodystrophy
3. Globoid body leukodystrophy (Krabbe disease)
4. Kufs form of lipid storage disease
5. G_{M2} gangliosidosis
6. Wilson disease
7. Leigh disease
8. Gaucher disease
9. Niemann-Pick disease
10. Mucopolysaccharide encephalopathy
11. Mucopolipidosis type I
12. Polyneuropathies (Andrade disease, Fabry disease, porphyria, Refsum disease)
13. Mitochondrial diseases, particularly progressive external ophthalmoplegia and Leigh disease

14. CADASIL (see page 879)

In the encephalopathic forms of the metabolic and mitochondrial diseases (described below), the diagnosis is usually made only after symptoms have been present for months or years, the disease having been mistaken for some other condition. For example, one of our patients with metachromatic leukodystrophy, a 30-year-old man, began failing in college years and was later unsuccessful in holding a job because of carelessness and mistakes in his work and indifference, irritability, and stubbornness (clearly traceable to a mild dementia). Only when Babinski signs and loss of tendon reflexes in the legs were detected was the diagnosis entertained for the first time. By then he had been ill for nearly 10 years. Bosch and Hart described a patient with the onset of dementia at 62 years of age and drew attention to 27 other cases of adult-onset metachromatic leukoencephalopathy. Overt signs of neuropathy are usually lacking in adult-onset cases, but EMG and sural nerve biopsy will disclose the characteristic abnormalities. One of our adult patients with Wilson disease had been committed to a psychiatric hospital because of his paranoid tendencies and fighting with his family; the presence of a tremor and mild rigidity of the limbs had been attributed at first to phenothiazine drugs. In some of Griffin's cases of adrenomyeloneuropathy, a spastic weakness of the legs and sensory ataxia, progressing over several years, were the main clinical manifestations; a spinocerebellar degeneration was suspected. One of our patients with Kufs lipid storage disease began to deteriorate mentally in early adult life and only later showed an increasing rigidity with athetotic posturing of limbs and difficulty in walking; he succumbed to his disease after more than 10 years.

Cerebellar ataxia, polymyoclonus, and progressive blindness have been observed in several adolescents and adults with a variant of G_{M2} gangliosidosis; cherry-red macular spots provided the clue to diagnosis. Several such cases have been reported in the last decade, particularly among the Japanese ([Miyatake et al](#)). We have observed two adult patients with progressive spinal muscular atrophy who proved to have the hexosaminidase deficiency of Tay-Sachs disease; the process was clinically indistinguishable from motor neuron disease (Kugelberg-Welander disease in adolescents) but might have the additional features of ataxia and an intermittent and atypical psychosis.

Dementia, optic atrophy, mild cerebellar ataxia, and corticospinal signs have been features of several personally observed patients with Leigh disease who survived in a relatively helpless state for nearly 20 years. Kalimo and associates have reported a similar family. An asymmetrical corticospinal syndrome with areflexia had advanced so slowly in one of our cases of Krabbe disease that she was not disabled until past her sixtieth year.

Another of our patients, an adolescent with severe diffuse myoclonus and seizures and slight intellectual deterioration, was found after several years to have one of the rare variants of Gaucher disease. Another with dementia, rigidity, choreoathetosis, slight cerebellar ataxia, and Babinski signs had a variant of Niemann-Pick disease. For many years we had under observation a family with Gaucher disease, several members of which developed seizures, generalized myoclonus, supranuclear gaze palsies, and cerebellar ataxia in early adult life ([Winkelman et al](#)). Rarely, Gaucher disease may be associated with an early and severe parkinsonian syndrome.

We have had the experience of finding laboratory evidence of adrenal insufficiency in several young men with white matter lesions of the frontal lobes and other parts of the cerebrum; there was no bronzing of the skin, and earlier a diagnosis of multiple sclerosis or Schilder disease had been made. Eldridge and coworkers have described a large kindred with widespread noninflammatory degeneration of the cerebral and cerebellar white matter; individual members were thought to have multiple sclerosis before a pattern of autosomal dominant inheritance became evident (possibly CADASIL, page 879). Such cases are likely to be found in multiple sclerosis clinics. Adrenoleukodystrophy presenting in adult life as a spinocerebellar or olivopontocerebellar syndrome has already been mentioned.

These rare forms of inherited metabolic disease are notable for their chronicity and for the early prominence of a particular neurologic symptom or syndrome. Once the disease is established, however, there is nearly always evidence of involvement of multiple neuronal systems, reflected in a subtle or overt dementia, character disorder, or signs referable to cerebellar, pyramidal, extrapyramidal, visual, and peripheral nerve structures. *This multiplicity of neuronal system involvement is much more a feature of heritable metabolic disease than of degenerative disease, and the finding of such involvement should always provoke a search for an inherited metabolic disorder.* The dictum that tract involvement (corticospinal, cerebellar, peduncular, sensory, optic nerve) indicates a leukodystrophy and that “gray matter” signs (seizures, myoclonus, dementia, retinal lesions) indicate a poliodystrophy is useful mainly in the early stages of a disease. Some of the lysosomal storage diseases affect both galactolipids (galactocerebrosides and sulfatides) and gangliosides; hence both white and gray matter are involved.

In concluding this discussion, which classifies the inherited monogenetic metabolic diseases in accordance with their salient clinical characteristics, the careful reader will appreciate its artificiality. Nearly every one of the diseases of each category may present some neurologic abnormality other than the ones we have emphasized, so that the potential number of variations is almost limitless. However, it is hoped that the plan presented here—of thinking of these diseases in reference to age periods and syndromic relationships—will be of heuristic value and facilitate clinical study of this extremely difficult part of neurologic medicine.

MITOCHONDRIAL DISORDERS

The diseases included under this heading are so diverse and involve so many parts of the nervous system that the clinical entities by which they are identified cannot be easily addressed in any one part of the book. In their heterogeneity and complex overlapping relationships, these diseases are unlike the more common, discrete clinical entities that are caused by nuclear genetic mutations. As stated in the introduction to this chapter, the neural damage in the mitochondrial diseases appears to derive from defects in the energy-producing systems of many cells and organs. This diversity is evident not only in the details of clinical presentation but also in the age at which symptoms first become apparent and the presence or absence of dysmorphic features, and—what is most intriguing—sometimes in the abrupt onset of illness. Most of this variability is understandable from the principles of mitochondrial genetics already outlined. Fortunately for the clinician, the most important of these diseases are expressed in several recognizable core syndromes and a few variants thereof. It is this perspective that we have found to be most useful clinically. A number of acronyms formed from the initial letters of the main clinical features have been used to designate these syndromes (MERRF, MELAS, PEO, NARP, etc.), as summarized in [Table 37-7](#). The addition of certain dysmorphic features, including short stature, endocrinopathies, particularly diabetes, and a number of other systemic abnormalities discussed further on, aids in diagnosis (see page 1045).

Syndromes	Common mitochondrial gene mutation	Age of onset	Typical features
Ragged red fiber (myopathy)	Point mutation at 1291	+	+
Progressive external ophthalmoplegia (PEO) and Kearns-Safer variant	Heteroplasmic deletion or point mutation at 1641	+	+
Long QT syndrome, tall T-wave syndrome and NARP	Point mutation at 3243	+	+
Myoclonic epilepsy and ragged red fiber in muscle (MERRF)	Point mutation at 1351	+	+
Myoclonic epilepsy, ragged red fiber, ataxia, and deafness (MELAS)	Point mutation at 1291	+	+
Leigh syndrome (encephalopathy)	Point mutation at 1651, 1671, or 1678	+	+
Myoclonic epilepsy, ragged red fiber, ataxia, and deafness (MELAS)	Point mutation at 1291	+	+

Table 37-7 The major categories of mitochondrial disorders

The best-characterized member of this group of diseases is a symmetrical proximal myopathy that can occur in isolation or in combination with CNS dysfunction. In 1966, Shy and coworkers described the histochemical and electron-microscopic abnormalities of the muscle mitochondria in a childhood myopathy, which they called *meagaconial* (meaning marked enlargement of the mitochondria) or *pleoconial* (an abundance of mitochondria). Later this change came to be known as “ragged red fibers,” so named because of the subsarcolemmal and intermyofibrillar collections of membranous (mitochondrial) material in many of the type 1 (red) fibers, visualized in Gomori trichrome– stained sections of frozen muscle. This change in muscle, sometimes asymptomatic, is a manifestation of several of the mitochondrial diseases of the nervous system as well. At the same time, it should be understood that most neurologic disorders designated as “mitochondrial” show no histologic or ultrastructural abnormalities in muscle mitochondria. Many patients with mitochondrial abnormalities show elevations of lactate or lactate-to-pyruvate ratios in the blood and CSF as a result of the respiratory chain abnormalities. These elevations are most prominent after exercise, infection, or alcohol ingestion, and—in some conditions—are capable of inducing recurrent ketoacidotic coma, which may be the main manifestation of a mitochondrial disease. Leigh syndrome and MELAS also have a marked tendency to exhibit elevations of lactate; however, the diagnosis of either cannot be excluded in the presence of normal levels, even after provocation by exercise. Using phosphorus MRI scans, one can compare levels of inorganic phosphate to phosphocreatine levels in muscle; in genetic muscle diseases of several

types, this ratio increases but it is highest in those of mitochondrial origin.

Although the mitochondrial diseases are considered here as a group, individual ones are of necessity mentioned in other chapters. Thus, the syndrome that combines epilepsy, deafness, and developmental delay with ragged red muscle fibers (myoclonic epilepsy with ragged red fibers, or MERRF) has already been discussed in [Chap. 16](#), on epilepsy. The syndrome of progressive external ophthalmoplegia (PEO) was discussed with other abnormalities of eye movement ([Chap. 14](#)); lactic acidosis and stroke-like episodes (MELAS) was considered in [Chap. 34](#), with the cerebrovascular diseases; and Leber hereditary optic neuropathy, with other causes of visual loss ([Chap. 13](#)). The Leigh syndrome, a symmetrical subacute necrotizing encephalomyelopathy, usually with lactic acidosis, also has a number of complex relationships—in this instance, different degrees of a mitochondrial abnormality cause several disparate clinical presentations. For each of the aforementioned core syndromes, a wider clinical experience will bring to light an individual or a family in whom some other mitochondrial disorder is associated. Also, fragmentary subsyndromes of each of the main types are known to occur, with onset from childhood to early adult life. It serves little purpose, therefore, to catalogue all of these linkages. Only the main and best characterized syndromes listed in [Table 37-7](#) are described. The most common combinations have been of Kearns-Sayre syndrome with MELAS or with MERRF, progressive ophthalmoplegia with MERRF, and MERRF with MELAS.

We prefer to avoid the issue of what best defines a mitochondrial disorder—its genetic defect, the biochemical disorder, or the clinical syndrome. The clinician assigns this term to particular combinations of a genetic mutation of mitochondrial DNA and certain clinical features that define syndromes; the biochemical changes are best viewed as markers of the inadequate energy-producing mechanisms of the mitochondrial machinery.

Mitochondrial Myopathies

The mildest form of mitochondrial myopathy may cause only a benign proximal weakness that tends to be more severe in the arms. Exercise intolerance is reported in half or more of these patients. There are adult-onset variants, but careful questioning usually elicits a lifelong exercise intolerance (weakness, discomfort, exertional dyspnea, and tachycardia), which is so slowly progressive that the patient can lead a relatively normal life for decades. Rare patterns include a fascioscapulohumeral or limb-girdle pattern of weakness as well as a recurrent exertional myoglobinuria. Some patients develop progressive external ophthalmoplegia (PEO) several years after the weakness becomes evident. Several mutations have been associated with a pure or predominant myopathy syndrome, the most common being located at position 3250 of the mitochondrial genome. Variants such as combined skeletal weakness and cardiomyopathy are referable to other loci.

At the more severe end of the spectrum is an infantile myopathy in which weakness and lactic acidosis become evident in the first week of life and are fatal by 1 year. Many of these patients and some families have a history of renal dysfunction combined with weakness of early onset. The muscle tissue shows numerous ragged red fibers, and cytochrome oxidase activity is virtually absent. DiMauro and others have described an apparently reversible form, which requires ventilatory support and gastric feeding but improves clinically with increasing age of the patient; the lactic acidosis is lost by age 2 or 3 years. In the childhood cases, the deficiencies in cytochrome oxidase suggest a defect in mitochondrial genes, but none has been found.

The histologic feature that unites the mitochondrial myopathies is the presence of so-called ragged red fibers. This finding in other mitochondrial diseases, such as PEO and MERRF, gives added credibility to the diagnosis of a mitochondrial disorder in any case where weakness is coupled with exercise intolerance, excess lactate, and a family history of similar problems. Also, the presence of ragged red fibers differentiates the mitochondrial myopathies from the glycogenoses. It bears repeating, however, that ragged red fibers are rare in infants and young children, even in those with confirmed mitochondrial disease.

Progressive External Ophthalmoplegia and Kearns-Sayre Syndrome

The combination of progressive ptosis and ophthalmoplegia is a common manifestation of mitochondrial disease. Usually there is no diplopia or strabismus or at most only transient diplopia, despite slightly dysconjugate gaze. We have been impressed at how long the illness can exist before it brings the patient to a physician.

Progressive external ophthalmoplegia bears a close relationship to the Kearns-Sayre syndrome of retinitis pigmentosa (onset before age 20), ataxia, heart block, and elevated CSF protein; sensorineural deafness, seizures, or pyramidal signs may be added (page 1502). The CNS syndromes of MELAS or MERRF (see further on) may also be combined occasionally with PEO.

Subacute Necrotizing Encephalomyelopathy (Leigh Disease; SNE)

This is a familial or sporadic mitochondrial disorder with a wide range of clinical manifestations. Some cases display a maternal pattern of inheritance. The onset in more than half the cases is in the first year of life, mostly before the sixth month, but late-onset varieties, with an even greater heterogeneity of presentation in young adulthood, are also known. As with some of the other mitochondrial diseases, the onset of neurologic symptoms is usually subacute or abrupt, sometimes precipitated by a febrile episode or a surgical operation.

In infants, loss of head control and other recent motor acquisitions, hypotonia, poor sucking, anorexia and vomiting, irritability and continuous crying, generalized seizures, and myoclonic jerks constitute the usual clinical picture. If the onset is in the second year, there are difficulties in walking, ataxia, dysarthria, psychomotor regression, tonic spasms, characteristic respiratory disturbances (episodic hyperventilation, especially during infections, and periods of apnea, gasping, and quiet sobbing), external ophthalmoplegia, nystagmus, and disorders of gaze (like those of Wernicke disease), paralysis of deglutition, and abnormal movements of the limbs (particularly dystonia but also jerky, choreiform movements and ataxia). Mild cases, showing developmental delay, have been mistaken for cerebral palsy. Peripheral nerves are involved in some cases (areflexia, weakness, atrophy, and slowed conduction velocities); in a few, autonomic failure is the most prominent feature. In some children the disease is episodic; in others it is intermittently progressive and quite protracted, with exacerbation of neurologic symptoms in association with nonspecific infections. The CSF is usually normal, but the protein content may be increased.

The pathologic changes take the form of bilaterally symmetrical foci of spongy necrosis with myelin degeneration, vascular proliferation, and gliosis in the thalami, midbrain, pons, medulla, and spinal cord. The basal ganglia are characteristically but not invariably affected. Also, there may be a demyelinating type of peripheral neuropathy. In their distribution and histologic appearance, the CNS lesions resemble those of Wernicke disease (thiaminosis) except that the lesions of SNE tend to be more extensive—sometimes involving the striatum—and they tend to spare the mammillary bodies. The lesions, particularly those of the lenticular nuclei and brainstem, may be seen in CT scans and are strikingly demonstrated by MRI. The histochemical appearance of muscle is normal, although electron microscopy may show an increased number of mitochondria.

The clinical boundaries of Leigh disease have not been defined precisely. A familial disorder of infancy and early childhood—referred to as bilateral striatal necrosis and associated with dystonia, visual failure, and other neurologic defects—is probably a variant of Leigh disease. The same may be true for an obscure adult-onset syndrome of progressive dementia from a thalamic lesion, showing necrosis, vascular proliferation, and gliosis.

The mitochondrial gene mutation most often associated with the Leigh syndrome is also considered in relation to the NARP syndrome discussed below. The close relationship between the two syndromes re-emphasizes the point that several mitochondrial mutations appear to give rise to the same clinical and pathologic picture of a subacute necrotizing encephalopathy.

Neuropathy, Ataxia, Retinitis Pigmentosa Syndrome (NARP) Leigh syndrome exemplifies to a remarkable degree the heterogeneity of abnormalities that may be associated with cytochrome oxidase deficiency due to a single mitochondrial gene mutation. A minor transversion error, the substitution of one amino acid in the mitochondrial DNA at position 8993, also gives rise to a maternally inherited syndrome of sensory neuropathy, ataxia, and retinitis pigmentosa (NARP). It may include developmental delay, seizures, and proximal muscle weakness. This gene abnormality creates an error in the ATPase-6 of complex V of the mitochondrial respiratory chain. The severity of the NARP syndrome corresponds to the amount of aberrant DNA in the mitochondrial genome; when the mutation involves over 90 percent of mitochondrial DNA, it produces the more severe phenotype of the Leigh syndrome (SNE). Santorelli and colleagues found that 12 of 50 patients with Leigh syndrome from 10 families displayed the 8993 point mutation. Within one kindred, the mitochondrial aberration may manifest itself as mild developmental delay, NARP, the full-blown Leigh syndrome, or early death with lactic acidosis. These differences in severity are thought to result from the protective effect of even small amounts of the normal mitochondrial genome. The first manifestations of disease may not appear until adulthood, although it begins only rarely after age 20. The similarities to Refsum disease are discussed on page 1421.

Further confounding the understanding of this disease complex is the observation that many patients with the Leigh syndrome have a pyruvate dehydrogenase (usually X-linked) or pyruvate decarboxylase deficiency, whereas others have the cytochrome oxidase deficiency, which is common to many mitochondrial disorders and inherited usually as an autosomal recessive trait. But Leigh syndrome patients with the 8993 mutation tend to have neither of these enzymatic deficiencies.

Bridging these complex cases are children with cytochrome oxidase deficiency who have psychomotor retardation, slowed growth, and lactic acidosis, some with and others without the striatal or brainstem spinal necroses of Leigh syndrome.

Congenital Lactic Acidosis and Recurrent Ketoacidosis

Certain types of organic acidemia, occurring in early infancy and of unproved genetic etiology, have already been mentioned (page 992). Here reference is made to those few cases that are associated with deletions of mitochondrial DNA. The syndrome has consisted of *psychomotor regression* and *episodic hyperventilation, hypotonia, and convulsions* with intervening periods of normalcy. Choreoathetosis or progressive ophthalmoplegia have been added in a few cases. Some children are also dysmorphic, with a broad nasal bridge, micrognathia, posteriorly rotated ears, short arms and fingers, and other features. A synopsis of such cases is given by [De Vivo and coworkers](#). Death usually occurs before the third year. The important laboratory findings are acidosis with high lactate levels and hyperalalinemia. The few cases that have been examined postmortem are found to have necrosis and cavitation of the globus pallidus and cerebral white matter, as occurs in SNE. Probably most cases of this type are due to disorders of the mitochondrial respiratory chain, particularly of the pyruvate- decarboxylase complex. The diagnosis can be made by the finding of ragged red fibers in muscle or by measurement of the enzyme activity. It must be distinguished from the several diseases of infancy that are complicated by lactic acidosis.

Myoclonic Epilepsy with Ragged Red Fiber Myopathy (MERRF)

This is perhaps the most distinctive mitochondrial disease, presenting as it does with progressive myoclonic epilepsy or myoclonic ataxia. These cases, as was noted in [Chap. 6](#), must be differentiated from several entities with a predictable clinical course, such as juvenile myoclonic epilepsy, Unverricht-Lundborg disease, Lafora-body disease, Baltic myoclonus, and neuronal ceroid-lipofuscinosis, discussed earlier in this chapter. Tsairis and colleagues were the first to describe the connection between familial myoclonic epilepsy and mitochondrial changes in muscle, and numerous variants of this core syndrome have been described since their report.

In our limited experience with this disease, myoclonus in a child or young adult is the most typical feature and is elicited by startle or by movement of the limbs. The nature of the seizures varies but includes drop attacks, focal epilepsy, or tonic-clonic types, some of which are photosensitive. Ataxia tends to worsen progressively, eclipsing the myoclonus and seizures in some instances and remaining a minor feature in others. The myopathy is usually inapparent or mild. The presence of mitochondrial muscle abnormalities is necessary for clinical diagnosis. To this constellation may be added any of the other elements of the mitochondrial diseases that have already been cited, including deafness (present in the cases we have seen), mental decline, optic atro-phy, ophthalmoplegia, cervical lipomas, short stature, or neuropathy.

Most cases are familial and display maternal inheritance, but the age of onset may vary and affected individuals have been reported with symptoms beginning as late as the sixth decade. Almost always the latter represent the mildest cases, with only myoclonic epilepsy. Those with onset in the first decade tend to be more severely affected and die before the third decade. As with the other mitochondrial processes, the quantitative burden of mutant DNA has been related to the time of onset and severity of the disease. Eighty percent of patients with MERRF have a point mutation of the mitochondrial genome at locus 8344, which codes for a transfer RNA, and, conversely, most patients with this mutation will have MERRF, including those with crossover features of the Leigh syndrome.

Mitochondrial Myopathy, Encephalopathy, Lactic Acidosis, and Stroke-Like Episodes (MELAS)

In patients with this syndrome, normal early development is followed by poor growth, focal or generalized seizures, and recurrent acute episodes that resemble strokes or prolonged transient ischemic attacks. The stroke deficits often improve but in some cases lead to a progressive encephalopathy. Some patients have hemicranial headaches that cannot be distinguished from migraine, and others suffer repetitive vomiting or episodic lactic acidosis. If there are any characteristic features, they take the form of an unusual clinical pattern of focal seizures, sometimes prolonged, which herald a stroke and have a unique radiographic pattern involving the cortex and immediate subcortical white matter. The CT may show numerous low-density regions that have no clinical correlates. Most patients have ragged red muscle fibers, but only rarely is there weakness or exercise intolerance.

As with the MERRF syndrome, approximately 80 percent of MELAS cases are related to a mitochondrial mutation occurring at the 3243 site, or, in a few instances, at an alternative locus that also codes for a segment of transfer RNA. Maternal inheritance is common but sporadic cases are well known. In the survey conducted by [Hammans and coworkers](#), only half of the instances of the 3243 mutation were associated with the MELAS syndrome. The finding of an abnormal mitochondrial genome in the endothelium and smooth muscle of cerebral vessels has been suggested as a basis for the strokes and migraine headaches.

The Diagnosis of Mitochondrial Disorders

If there are any characteristic neurologic signs of a mitochondrial disorder, they fall into four broad groups: (1) combinations of ataxia, seizures, and myoclonus, typified by the MERRF syndrome; (2) migraine-like headaches, recurrent small strokes, and preceding seizures, typified by the MELAS syndrome; (3) ophthalmoplegia and retinitis pigmentosa with polyneuropathy, optic atrophy (Leber type), or deafness (Kearns-Sayre syndrome); and (4) a myopathy that is slowly progressive or fluctuating in severity. These may be combined with dementia, lactic acidosis, short stature, ptosis, pigmentary retinal degeneration, and cardiac conduction defects (as in the Kearns-Sayre syndrome) as well as with multiple symmetrical lipomas. Peripheral nerve involvement, although common in these disorders, is usually asymptomatic; autonomic failure may be a manifestation. A panoply of visceral dysfunctions may be associated with the mitochondrial disorders—including bone marrow changes of sideroblastic anemia, renal tubular defects, endocrinopathies (diabetes, hypothyroidism, deficiency of growth hormone), hepatopathy, cardiomyopathy, and recurrent vomiting with intestinal pseudo-obstruction. Diabetes has been a marker in several of the early-onset MELAS and MERRF cases that we have seen, but less often when the first manifestations were in adulthood.

The investigation of a suspected case of mitochondrial disease begins with an exploration of the family history for childhood diseases, including neonatal death, unexplained seizure disorders, and progressive neurologic deficits of the types already described. Unexplained deafness or diabetes in family members should also raise the suspicion of a mitochondrial disorder. Commercial tests of leukocytes for the more frequent mitochondrial point mutation sites (3243, 8993, and 8344 are the usual ones) are useful but reveal mutations in only about 15 percent of patients, even in those whose muscles contain an abundant amount of mutant mitochondrial genome. Resting and postexercise lactate and pyruvate determinations are also helpful. A muscle biopsy is probably the next step and may disclose several basic abnormalities; ragged red fibers can be recognized by use of the modified Gomori stain on frozen material, and the absence of succinate dehydrogenase and cytochrome oxidase, by appropriate histochemical staining. In cases of suspected Leigh syndrome or MELAS, the CT or MRI may show some of the characteristic lesions; in the other mitochondrial disorders there are often focal nondescript hyperintensities on T2-weighted MRI, atrophy, lucencies, or calcification. Sampling of chorionic villi for prenatal diagnosis may show mutant mitochondrial DNA, but this information is not entirely dependable.

It should be evident from the foregoing discussion that normal findings in any of these tests, including the muscle biopsy, do not exclude mitochondrial disease. In the final analysis, it is the clinical syndrome, family history, and any corroborating evidence of a mitochondrial disorder or its genetic representation that is diagnostic. The review of Jackson and coworkers suggests that isolated phenomena such as dementia, muscle weakness, epilepsy, nerve deafness, migraine with strokes, small stature, myoclonic epilepsy, and cardiomyopathy should prompt consideration of a mitochondrial disorder when no other explanation is evident.

Clinical Characteristics of the Severely Retarded

Differentiation of Types of Retardation: Clinical Approach

Hereditary Mental Retardations

Autism (Kanner-Asperger Syndrome; Autistic Spectrum Disorders)

Management of Mental Retardation

Chapter References

Subsumed under this broad heading is a diversity of developmental malformations and diseases acquired during the intrauterine period of life. They number in the hundreds, according to the tabulation of Dyken and Krawiecki, although many of them are very rare. Taxonomically they include many unrelated pathologic processes of different origins: some stem from germplasm abnormalities; others are associated with triplication, deletion, and translocations of chromosomes; and probably some are inherited on a polygenic basis. Still others are due to the effects of a variety of noxious agents acting at different times on the immature nervous system, i.e., during the embryonal, fetal, and paranatal periods of life.

It would be intellectually satisfying if all the states that originate in the intrauterine period could be separated into genetic (hereditary) or nongenetic (congenital) forms, but in many instances the biologic information and the pathologic changes in the brain at this early age do not allow such a division. For example, among the many diseases in which the neural tube fails to close (rachischisis), more than one member of a family may be affected; but it cannot be stated whether a genetic factor is operative or an exogenous factor, such as folic acid deficiency, has acted upon several members during a succession of pregnancies of one mother. Even what appears to be an outright malformation of the brain may be no more than a reflection of the timing of a pathologic process that has affected the nervous system and other organs early in the embryonal period, derailing later processes of development. *Teratology*, the scientific study of neurosomatic malformations, is replete with such examples.

The authors do not wish to imply that medical and biologic ideas about these conditions are completely unsettled, for there are diseases, transmitted from one generation to another, that affect both of the identical (monovular) twins and only one of the fraternal (biovular) twins. In these, a genetic determinant cannot be questioned, for the unaffected fraternal twin shares the same intrauterine environment as the twin sibling. Then, too, a few diseases destroy parts of the brain in utero in specific ways; others affect it in nonspecific ways but leave little doubt as to the action of an exogenous pathogen.

As to the frequency of developmental disorders, Smith (see [K. L. Jones](#)) points out that a single malformation, usually of no clinical significance, occurs in 14 percent of newborns. Two malformations appear in 0.8 percent, and in this group, a major defect is five times more frequent than in the normal population. Three or more malformations are found in 0.5 percent of newborns, and in this latter group, more than 90 percent have one or more major abnormalities (defined as structural abnormalities of prenatal origin that seriously interfere with viability or physical well-being). The figures for major congenital malformations, compiled by [Kalter and Warkany](#), are somewhat higher. What is most important for the neurologist is the fact that the nervous system is involved in most of these infants with major malformations. In fact, about 40 percent of deaths during the first postnatal year are in some manner related to prenatal malformations of the central nervous system (CNS).

A perusal of the following pages makes it evident that there is a great variety of structural defects of the nervous system in early life; in fact, every part of the brain, spinal cord, nerves, and musculature may be affected. However, certain principles are applicable to the entire group. *First*, the abnormality of the nervous system is frequently accompanied by an abnormality of some other structure or organ (eye, nose, cranium, spine, ear, and heart), which relates them chronologically to a certain period of embryogenesis. Conversely, the presence of these malformations of nonnervous tissues suggests that an associated abnormality of the nervous system is developmental in nature. However, this principle is not inviolable; in certain maldevelopments of the brain, which must have originated in the embryonal period, all other organs are normal. One can only assume that the brain is more vulnerable than any other organ to prenatal as well as natal influences. Perhaps this occurs because the nervous system, of all organ systems, requires the longest time for its development and maturation, during which it is susceptible to disease. *Second*, a maldevelopment of whatever cause should be present at birth and remain stable thereafter, i.e., be nonprogressive; again, this principle requires qualification—the abnormality may have affected parts of the brain that are not functional at birth, so that an interval of time must elapse postnatally before the defect can express itself. *Third*, birth should have been nontraumatic and the pregnancy uncomplicated by infection or other injurious event. However, the occurrence of a traumatic birth is not proof of a causative relationship between the injury (or infection) and the abnormality, because a defective nervous system may itself interfere with the birth or the gestational process. *Fourth*, if the birth abnormality has occurred in other members of the family of the same or previous generations, it is usually genetic—although, as noted above, this does not exclude the possible adverse effects of exogenous agents. *Fifth*, many of the teratologic conditions that cause birth defects pass unrecognized because they end in spontaneous abortions. For example, defects due to chromosomal abnormalities occur in about 0.6 percent of live births, but such defects are found in more than 5 percent of spontaneous abortions at 5 to 12 weeks gestational age. *Sixth*, low birth weight and gestational age, indicative of premature birth, increase the risk of mental subnormality, seizures, cerebral palsy, and death.

Regarding *etiology*, which is really the crux of the problem of birth defects, some order and classification have emerged. In general, malformations may be subdivided into four groups: (1) one in which a single mutant gene is responsible (2.25 per 1000 live births); (2) one in which birth defects are associated with chromosomal aberrations; (3) a group comprising defects attributable solely to exogenous factors (a virus or other infectious agent, irradiation, or toxin); and (4) the largest group of all (60 percent of cases), in which no cause can be identified. It has been stated that true malformations are due to fundamental endogenous disturbances of cytogenesis and histogenesis occurring in the first half of gestation, and that exogenous factors, which destroy brain tissue but do not cause malformations, operate in the second half. The potential fallacy of this division is obvious. An exogenous lesion occurring during the embryonal period may not only destroy tissue but derail the neuronal migrations of normal development.

A textbook on principles of neurology is not the place in which to present a detailed account of all the hereditary and congenital developmental abnormalities that

might affect the nervous system. For such details, the interested reader should refer to several excellent monographs. Three that the authors recommend are Brett's *Pediatric Neurology*, Berg's *Principles of Child Neurology*, and Lyon and Evrard's *Neuropediatric*. In this chapter we sketch only the major groups and discuss in detail a few of the more common disease entities. The classification in [Table 38-1](#) adheres to a *grouping in accordance with the main presenting abnormality or abnormalities*. Represented here are the common problems that lead families to seek consultation with the pediatric neurologist: (1) structural defects of the cranium, spine, and limbs, and of eyes, nose, ears, jaws, and skin; (2) disturbed motor function—taking the form of retarded development or abnormal movements; (3) epilepsy; and (4) mental retardation. The following discussion focuses on each of these clinical states.

I. Neurologic disorders associated with craniospinal deformities	II. The phakomatoses
A. Enlarged head	A. Tuberous sclerosis
1. Hydrocephalus	B. Neurofibromatosis
2. Hydroanencephaly	C. Epilepsy syndromes with CNS abnormalities
3. Macrocephaly	
B. Craniosynostosis	III. Structural developmental abnormalities of the nervous system
1. Craniosynostosis	A. Fetal cortical dysplasia
2. Hydrocephalus	B. MRSA syndrome
3. Hydroanencephaly	C. Congenital agenesis of ears
C. Disruption of neural formation and migration	D. Other congenital developmental abnormalities (Hirschmann syndrome, retinoblastoma, neuroblastoma, etc.)
1. Anencephaly	IV. Congenital abnormalities of motor function (cerebral palsy)
2. Spina bifida	A. Subependymal cysts (hemorrhage)
3. Myelomeningocele	B. Cerebral atrophy (atrophy)
4. Spina bifida	C. Spina bifida: Arnold-Chiari malformation, and spina bifida
D. Disruption of neural formation and migration	D. Congenital developmental disorders (Hirschmann syndrome, retinoblastoma, neuroblastoma, etc.)
1. Anencephaly	E. Congenital atrophy
2. Spina bifida	F. The Rasmussen syndrome
3. Myelomeningocele	V. Perinatal and neonatal infections
4. Spina bifida	A. Botulism
5. Disruption of neural formation and migration	B. Cerebral ischemia (stroke)
6. Disruption of neural formation and migration	C. Congenital toxoplasmosis
7. Disruption of neural formation and migration	D. HIV infection and AIDS
8. Disruption of neural formation and migration	E. Neurosyphilis
9. Disruption of neural formation and migration	F. Other viral and bacterial infections

Table 38-1 Classification of congenital neurologic disorders

NEUROLOGIC DISORDERS ASSOCIATED WITH CRANIOSPINAL DEFORMITIES

A majority of the disorders in this group are due to a genetic error, including those with a specific chromosomal abnormality, or to some unknown factor. One has only to walk through an institution for the mentally retarded to appreciate the remarkable number and diversity of physical disfigurements that attend abnormalities of the nervous system. Smith, in the third edition of his monograph on the patterns of human malformations, listed 345 distinctive syndromes; in the fourth edition (edited by [K. L. Jones](#), 1988), many new ones were added. Indeed, a normal-appearing individual stands out in such a crowd and will frequently be found to have an inherited metabolic defect or birth injury.

The intimate relationship between the growth and development of the cranium and that of the brain deserves comment. In embryonic life the most rapidly growing parts of the neural tube induce special changes in and at the same time are influenced by the overlying mesoderm (a process known as *induction*); hence abnormalities in the formation of skull, orbits, nose, and spine are regularly associated with anomalies of the brain and spinal cord. During early fetal life the cranial bones and vertebral arches enclose and protect the developing brain and spinal cord; throughout the period of rapid brain growth, as pressure is exerted on the inner table of the skull, the latter accommodates to the increasing size of the brain. This adaptation is facilitated by the membranous fontanelles, which remain open until maximal brain growth has been attained; only then do they ossify (close).

In addition, stature is controlled by the nervous system, as shown by the fact that a majority of mental retardates are also stunted physically to a varying degree. Thus disorders of craniovertebral development assume importance not merely because of the physical disfigurement but also because they often reflect an abnormality of the underlying brain and spinal cord, i.e., they become diagnostic signs.

Cranial Malformations at Birth and in Early Infancy

Certain alterations in size and shape of the head in the infant, child, or even adult always signify a pathologic process that affected the brain before birth or in early infancy. The size of the cranium reflects the size of the brain; therefore the tape measure is one of the most useful tools in pediatric neurology; no examination in a neurologically affected child is complete without a measurement of the circumference of the head. Graphs of the head circumference in males and females, from birth to 18 years of age, have been compiled by [Nellhaus](#). A newborn whose head circumference is below the third percentile for age and sex and whose fontanelles are closed may be judged to have a developmental abnormality of the brain. A head that is normal in size at term but fails to keep pace with body length reflects a later failure of growth and maturation of the cerebral hemispheres (microcephaly and microencephaly).

Enlargement of the Head (Macrocephaly) This can be due to hydrocephalus, hydranencephalus (as defined below), or excessive brain growth (megalo- or macroencephaly). The *hydrocephalic head* is distinguished by several features—frontal protuberance, or bossing, a tendency for the eyes to turn down so that the sclerae are visible between the upper eyelids and iris (sunset sign), thinning of the scalp and prominence of scalp veins, separation of the cranial sutures, and a “cracked pot” sound on percussion of the skull. Hydrocephalus usually comes to medical attention because of an expanding cranium that exceeds normal dimensions for age. The usual causes are type II Chiari malformation, hereditary aqueductal stenosis, and prenatal infections, e.g., toxoplasmosis. These disorders are discussed further on and in [Chap. 30](#).

The *hydranencephalic head* (hydrocephalus and destruction or failure of development of parts of the cerebrum) is often associated with enlargement of the skull. When it is transilluminated with a strong flashlight in a darkened room, the fluid-filled region of the cranium glows like a jack-o'-lantern. Hydranencephaly is not a well-defined entity. It can be caused by intrauterine vascular occlusion or diseases such as toxoplasmosis and cytomegalovirus (CMV) disease, which destroy parts of each cerebral hemisphere. The lack of brain tissue reduces resistance to intraventricular pressure, permitting great enlargement of both lateral ventricles; it is especially marked if there is an added hydrocephalic state due to interference with cerebrospinal fluid (CSF) circulation. This type of destruction of the cerebral mantle in the embryonal period may lead to the formation of huge defects, with apposition of ventricular and pial surfaces (*porencephaly*) and subsequent failure of development (evagination) of the brain. Yakovlev and Wadsworth referred to the localized failure of evagination as *schizencephaly* and postulated that it was the result of a focal developmental defect in the wall of the cerebral mantle. They based their interpretation on the finding of malformed cortex in the margins of the defect, but this might indicate only that the lesion preceded neuronal migration. Levine and coworkers have attributed it to a destructive, possibly ischemic lesion occurring in the first few weeks of gestation, at a time when neuronal migration was incomplete. We favor the latter explanation and describe it further in relation to the cerebral palsies. In either event, the lack of resistance of the defective cerebral mantle to ventricular pressure expands the brain and cranium.

The *macrocephalic head* (a large head with normal or only slightly enlarged ventricles) may be indicative of an advancing metabolic disease that enlarges the brain, as in *Alexander disease*, *spongy degeneration of infancy*, and *later phases of Tay-Sachs disease*. *Subdural hematomas* may also enlarge the head and cause bulging of the fontanelles and separation of the sutures. In the latter condition, the infant is usually irritable and listless, taking nourishment poorly. Infants and children with neurofibromatosis, osteogenesis imperfecta, and achondroplasia also have enlarged heads; in the last condition some degree of hydrocephalus appears to be responsible. Ultrasonography, which can be performed in the prenatal and neonatal periods, is usually diagnostic in all these cranial enlargements. Also MRI and CT scanning will disclose the size of the ventricles and the presence of subdural blood or fluid (hygroma).

Finally, *agenesis of the corpus callosum*, a common congenital defect, may be associated with macrocephaly and varying degrees of mental impairment, optic defects, and seizures. In a series of 56 patients with agenesis of the corpus callosum, Taylor and David reported the presence of epilepsy in 32 and varying degrees of mental retardation in 28; only 9 had no recognizable neurologic defects. Also noted was a high incidence of psychiatric disturbances in these patients. In such cases, CT scans and MRI reveal the characteristic “bat-wing” deformity of the ventricles. There is also asynchrony of electrical activity of the two cerebral hemispheres on the electroencephalogram (EEG). In a few of these patients, an autosomal dominant inheritance has been found ([Lynn et al](#)). Agenesis of the corpus callosum is also part of the Aicardi syndrome (see further on), the Andermann syndrome, and nonketotic hyperglycinemia.

Apart from patients with these pathologic states, there are individuals whose head and brain are enlarged but who are normal in all other respects. Many of these individuals come from families with large heads; Schreier and colleagues, who traced this condition through three generations of some families, declared it to be an autosomal dominant trait. This group represented 20 percent of 557 children referred to a clinic because of cranial enlargement ([Lorber and Priestley](#)).

Hemimegalencephaly This term refers to a marked enlargement of one cerebral hemisphere as a result of a developmental abnormality. The cortical gray matter and sometimes the basal ganglia are greatly increased in volume and weight. The cerebellum, brainstem, and spinal cord retain their normal dimensions. The cranium

may be misshapen or enlarged but is normal in size in some cases. Rarely, the face and body are enlarged on the side of the enlarged hemisphere. The cortex of the giant hemisphere is thick and disorganized. Neurons are in disarray and some are enlarged; in some places the natural lamination of the cortex is effaced. Nothing is known about causation, but apparently embryogenesis has been deranged at the stage of neuroblast formation.

Clinically, most affected individuals have been mentally retarded and some are epileptic. A degree of hemiparesis may be present, but severe hemispherical neurologic deficits are generally not reported. The hemimegalencephaly has been discovered at autopsy in a few individuals who had no mental or neurologic deficits.

Craniostenoses Some of the most startling cranial deformities are caused by premature closure of the cranial sutures (membranous junctions between bones of the skull). Such conditions are estimated to occur in 1 of every 1000 births, with a predominance in males ([Lyon and Evrard](#)). The growth of the cranium is inhibited in a direction perpendicular to the involved suture(s), with a compensatory enlargement in other dimensions, as allowed by the patent sutures. For example, when the lambdoid and coronal sutures are both affected, the thrust of the growing brain enlarges the head in a vertical direction (*tower skull*, or *oxycephaly*, also referred to as *turricephaly* and *acrocephaly*). The orbits are shallow, the eyes bulge, and skull films show islands of bone thinning (*Lückenschadel*). When only the sagittal suture is involved, the head is long and narrow (*scaphocephalic*), and the closed suture projects, keel-like, in the midline. With premature closure of the coronal suture, the head is excessively wide and short (*brachycephalic*). The nervous system is usually normal in these restricted craniostenoses. If this condition is recognized before 3 months of age, the surgeon can make artificial sutures that may permit the shape of the head to become more normal ([Shillito and Matson](#)). Once brain growth has been completed, nothing can be done. When several sutures (usually coronal and sagittal) are closed, so as to diminish the cranial capacity, intracranial pressure may increase, impairing cerebral function and causing headache, vomiting, and papilledema. Obviously an operation is then needed to increase the capacity of the skull. In craniostenoses that are combined with syndactyly (acrocephalosyndactyly or Apert syndrome), there are often added complications—mental retardation, deafness, convulsions, and loss of sight secondary to papilledema. The so-called clover-shaped skull is the most severe and lethal of the craniostenoses because of the associated developmental anomalies of the brain (see further on).

When, for any reason, an infant lies with the head turned constantly to one side (because of a shortened sternomastoid muscle or hemianopia, for example), the occiput on that side becomes flattened, as does the opposite frontal bone. The other occipital and frontal bones bulge, so that the maximum length of the skull is not in the sagittal but in the diagonal plane. This condition is called *plagiocephaly*, or *wry head*. Craniostenosis of one-half of a coronal suture may also distort the skull in this way.

Disturbances of Neuronal Migration

Neuroembryologic studies have identified several milestones of neuroblast formation, migration, cortical organization, neuron differentiation, and connectivity. Certain developmental anomalies have been traced to one or another of these stages of cytogenesis and histogenesis in the first trimester of gestation and to the growth and differentiation that take place in the second and third trimesters. Originally there is an excess of neurons, many of which degenerate during development—a process called apoptosis. There are recorded instances in which the full complement of neuroblasts and neurons fails to be generated. Or the emergence of two separate cerebral hemispheres may not occur (*holoprosencephaly*), or the bihemispherical brain may remain small (*microcephaly*). In other described specimens, a diminished number of neurons is less obvious than their failure to migrate to the cortical surface; they remain scattered through the mantle zone in sheets and heterotopic aggregates. One type of focal band-shaped subcortical heterotopia (“double-cortex”) with *micropolygyria* (an excessive number of abnormally small gyri) is X-linked, occurring only in females. It is expressed by a syndrome of mental retardation, seizures, delayed speech, and motor abnormalities. The cortex may fail to become sulcated—i.e., it is *lissencephalic* or may be defectively convoluted, forming microgyric and *pachygyric* (broad gyral) patterns. In yet other specimens, neuronal migration is normal for the most part, but small groups of neurons in particular regions may lag or present in regional *heterotopias* (focal dysgeneses) ([Fig. 38-1](#)). These are just now being recognized by MRI and are found to have a possible functional significance in such states as mental retardation, epilepsy, and dyslexia. Finally, the cortex may be normally formed and structured but there is a failure of differentiation of intra- and intercortical and interhemispherical connections, the most obvious one being agenesis of the corpus callosum.

Figure 38-1 Magnetic resonance imaging in the coronal plane in an infant with seizures. Deep in the white matter, adjacent to the lateral ventricle, is a large heterotopic aggregate of gray matter. Also, there appears to be an increased infolding of the cerebral cortex (polymicrogyria).

Since each phase of cerebral development is believed to be under genetic control, it comes as no surprise that aberrant development might also be genetic. Indeed, certain cases of lissencephaly have been traced to a defect on chromosome 17, double cortex to xq21, and periventricular heterotopias to x28. Some of the aforementioned cranial abnormalities, of which microcephaly is the most frequent, are secondary to anomalies of cerebral growth. Others—such as abnormalities of the eyes, root of nose, upper lip, ears, and limbs—may represent part of the basic developmental disorder.

The conjunction of cardiac, limb, gut, and bladder abnormalities with neurologic disorder indicates the time at which the insult takes place: cardiac abnormalities occur between the fifth and sixth week; extroversion of the bladder at less than 30 days; duodenal atresia, before 30 days; syndactyly, before 6 weeks; meningomyelocele, before 28 days; anencephaly, before 28 days; cleft lip, before 36 days; syndactyly, cyclopia, and holoprosencephaly, before 23 days.

With these elementary facts of neuroembryology in mind, the bases of the following clinical states are readily conceptualized: anencephaly, lissencephaly, holoprosencephaly, polymicrogyria and pachygyria, microcephaly, and special cranial and somatic abnormalities; each is described below.

There are also special types of tumors, thought to be the consequence of abnormal neuronal or glial development, and they should be mentioned here. They are variously termed gangliomas, dysembryoblastic neuroepitheliomas, and low-grade astrocytomas. Often they become manifest in the first year of life or even before birth. Their relatively slow growth and benign character suggest that some of them represent hamartomas rather than true neoplasms (see [Chap. 31](#)).

Anencephaly This is one of the most frequent and also most appalling congenital malformations of the brain. Its incidence is 0.1 to 0.7 per 1000 births, and females predominate in ratios of 3:1 to 7:1. The concordance rate is low, being the same in identical and fraternal twins, but the incidence of the malformation is several times the expected rate if one child in the sibship has already been afflicted. Anencephaly is more frequent in certain geographic areas, e.g., Ireland. Lacking are large portions of scalp, cranial bones, and brain, both cerebral cortex and white matter. All that is seen is a hemorrhagic nubbin of nerve, glial, and connective tissue. Brainstem, cerebellum, and spinal cord are present, but often they too are malformed, as are the heart and other organs (15 to 40 percent of cases). In anencephalics who survive for a few days (65 percent die in utero and almost 100 percent before the end of the first postnatal week), startle reactions may be observed, as well as movements of limbs, spontaneous respirations, pupillary light reactions, ocular movements, and corneal reflexes. In a few, avoidance reactions, crying, and feeding reflexes can be elicited.

This condition can be anticipated if the mother's serum levels of α -fetoprotein and acetylcholine esterase are elevated—even more reliably if testing is done on amniotic fluid. Positive tests should lead to ultrasound imaging of the fetus. Hydramnios is common. Apparently, the causes of anencephaly are multiple and include chromosomal abnormalities, maternal hyperthermia, and deficiencies of folate, zinc, and copper (see [Medical Task Force on Anencephaly](#) in the References). There is fairly secure evidence that supplemental intake of folic acid during the first trimester of pregnancy (i.e., from the time of conception) greatly reduces the incidence of anencephaly and myelomeningocele.

There are additional comments on anencephaly further on in this chapter, in the section on rachischisis.

Lissencephaly (Agyria), Holoprosencephaly, and Gyral Malformations Included under this heading are several forms of neuronal migratory defects. In the lissencephalies, cortical convolutions may be absent altogether and there is morphologic evidence of several types of neuroblast deficiency resulting from either generalized or restricted problems in neuronal migration. Such cases are of particular interest to neonatologists because of their associated physical abnormalities. The degree of impairment of neurologic function seldom allows longevity, so that relatively few examples are to be found in institutions for the mentally retarded. Seizures, poor temperature regulation, failure to accept nourishment, and apneic attacks combine to shorten life. The failures of migration are of varying degrees of severity. There may be a failure of neurons to form or migrate along glial guidelines to reach the more superficial layers of the cortex ([Bielschowsky](#) type); or the cortex, meninges, and eyes may fail to differentiate normally except for the dentate gyrus and hippocampus (Walker-Warburg type); or there may be relatively minor focal derangements of cortical migrations and lamination with heterotopias of neurons in the white matter.

In the complete lissencephalies, the cerebral ventricles enlarge due to a lack of the normal quantities of surrounding cerebral tissue. The cerebellar cortex is also abnormal. In some lissencephalic brains, there is slight sulcation presenting as abnormally broad or narrow convolutions, with thick, poorly laminated cortex; these are called *pachygyria* or *microgyria*, respectively, but the migratory abnormality is basically the same. The cerebellum is also abnormal with hypoplasia or aplasia involving the vermis or neocerebellum. In the *Dandy-Walker syndrome*, there is vermian hypoplasia with or without hydrocephalus, agenesis of the corpus callosum, and cerebral cortical dysgeneses ([Landrieu](#)). This defect, which is identified by the cystic enlargement of the fourth ventricle, is discussed further on, with the dysraphic neural tube defects. That some instances of lissencephaly have a genetic basis (a defect in chromosome 17) has already been mentioned.

In the severe migratory defects, the cranium is small at birth. In one type, which is inherited as an autosomal recessive trait, there are subtle craniofacial features (short nose, small mandible, ear abnormalities, congenital heart disease). In another group, there is an associated familial congenital muscular dystrophy, placing the case between the Fukuyama and Walker-Warburg syndromes (see page 1507). Most cases are sporadic, and the infants seldom survive for long.

Alobar and lobar *holoprosencephalies* are other examples of neuronal migratory defects with craniofacial abnormalities in which development has gone awry in the fifth and sixth weeks of gestation (see [Volpe](#)). In these subtypes, the two cerebral hemispheres, either totally or only in part, form as a single telencephalic mass. In nearly every case the cerebral defect is expressed by a single eye (cyclopia) and absence of nose, imparting an astonishing but diagnostic appearance.

In a few of the foregoing malformations, a congenital infection with cytomegalovirus or rubella has been implicated ([Hayward et al](#)).

Microcephaly In the above-mentioned cerebral dysplasias, the cranium and brain are small, but there is also a primary form of hereditary microcephaly, called *microcephaly vera*, in which the head is astonishingly reduced in size (circumference less than 45 cm in adult life—i.e., 5 standard deviations below the mean). In contrast, the face is of normal size, the forehead is narrow and recedes sharply, and the occiput is flat. Stature is only moderately reduced. Such individuals can be recognized at birth by their anthropoid appearance and later by their lumbering gait, extremely low intelligence, and lack of communicative speech. Vision, hearing, and cutaneous sensation are spared. In one of our cases, by laborious effort using operant conditioning, it was possible to teach the patient the shapes of simple figures. His sister's brain, examined by R. D. Adams, was malformed and weighed only 280 g. Tendon reflexes in the legs are brisk, and the plantar reflexes may be extensor. Skull films show that the cranial sutures are present, as are convolutional markings on the inner table. There are two types of inheritance of microcephaly vera, autosomal recessive and sex-linked. The brain often weighs less than 300 g (normal adult range, 1100 to 1500 g) and shows only a few primary and secondary sulci. The cerebral cortex is thick and un laminated and grossly deficient in neurons. In a few reported cases, there has been an associated cerebellar hypoplasia or an infantile muscular atrophy. Lesser degrees of microencephaly have been associated with progressive motor neuron disease and degeneration of the substantia nigra ([Halperin et al](#)).

Evrard and associates have described a rare, special type of microcephaly which they call "radial microbrain." Birth is at term, but the infant dies in the first month of postnatal life. The sulcal pattern is normal, and neuronal arrangements in the cerebral cortex are normal as well. The defect appears to be in the small number of neurons that are generated, not in their migration.

Combined Cerebral, Cranial, and Somatic Abnormalities

As has been remarked, many diseases that interfere with cerebral development also deform the cranial and facial bones, eyes, nose, and ears. Such somatic stigmata therefore assume significance as indicators of altered cerebral structure and function. Moreover, they constitute irrefutable evidence that the associated neural abnormality is in the nature of a maldevelopment, either hereditary or the result of a disease acquired during the intrauterine period.

There are so many cerebrosomatic anomalies that one can hardly retain visual images of them, much less recall all the physicians' names by which they are known. Of necessity one turns to atlases, one of the best of which has been compiled by [Holmes](#) and colleagues and is based on clinical material drawn from the Fernald School and Eunice K. Shriver Center in Massachusetts. The reader may turn to this book or to the ones by [Gorlin](#) and colleagues and by [Jones](#) for specific information. Ford's *Diseases of the Nervous System in Infancy, Childhood, and Adolescence* is still a valuable reference, as is Jablonski's *Dictionary of Syndromes and Eponymic Diseases*.

There is some advantage in grouping these anomalies according to whether the extremities, face, eyes, ears, and skin are associated with a cerebral defect. The sheer number and variety of these anomalies permit only an enumeration of the more common ones and their most obvious physical characteristics. To identify a particular anomaly, one has recourse to the specialized monographs and atlases mentioned above. Unfortunately, apart from certain genetic linkages, no useful leads as to their origin have been forthcoming.

The Syndactylic-Craniocerebral Anomalies Commonly, fusion of two fingers or two toes or the presence of a tab of skin representing an extra digit may be seen at birth in an otherwise normal individual. However, as pointed out above, when syndactylism is of more severe degree and is accompanied by premature closure of cranial sutures, the nervous system usually proves to be abnormal as well. The general term *acrocephalosyndactyly* is used to describe the several combinations of craniostenotic and facial deformities and fusion of digits. The following descriptions include only the major features; most have, in addition, distinctive malformations of the orbits, ears, and palate.

1. *Acrocephalosyndactyly types I and II (typical and atypical Apert syndrome)*. Turribrachycephalic skull, syndactyly of hands and feet ("mitten hands," "sock feet"), moderate to severe mental retardation.
2. *Acrocephalosyndactyly III (Saethre-Chotzen syndrome)*. Transmission as an autosomal dominant trait, various types of craniostenosis, proximally fused and shortened digits, moderate degree of mental retardation; autosomal dominant.
3. *Acrocephalosyndactyly IV (Pfeiffer syndrome)*. Turribrachycephaly; broad, enlarged thumbs and great toes; partially flexed elbows (radiohumeral or radioulnar synostoses); mild and variable mental retardation; autosomal dominant inheritance.
4. *Acrocephalopolysyndactyly (Carpenter syndrome)*. Premature fusion of all cranial sutures with acrocephaly, flat bridge of nose, medial canthi displaced laterally, excess digits and syndactyly, subnormal intelligence.
5. *Acrocephalosyndactyly with absent digits*. High, bitemporally flattened head; absent toes and syndactylic fingers; moderate mental retardation.
6. *Acrocephaly with cleft lip and palate, radial aplasia, and absent digits*. Microbrachycephaly due to craniostenosis, cleft lip and palate, absent radial bones, severe mental retardation.
7. *Dyschondroplasia, facial anomalies, and polysyndactyly*. Keel-shaped skull and ridge through center of forehead (metopic suture), short arms and legs, postaxial polydactyly and short digits, moderate mental retardation.

In all the foregoing types of syndactylism and cranial abnormality, which may be regarded as variants of a common syndrome, the diagnosis can be made at a glance because of the deformed head, protuberant eyes, and abnormal hands and feet. The mental retardation proves to be variable, usually moderate to severe, but occasionally intelligence is normal or nearly so. The brain has been examined in only a few instances and not in a fashion to display fully the developmental abnormality.

Other Craniocephalic-Skeletal Anomalies Members of this group have distinctive anomalies of the cranium, face, and other parts, but craniostenosis is not a consistent feature.

1. *Craniofacial dysostosis (Crouzon syndrome)*. Autosomal dominant inheritance; variable degrees of craniosynostosis; broad forehead with prominence in the

anterior fontanel region; shallow orbits with proptosis; midline facial hypoplasia and short upper lip; malformed auditory canals and ears; high, narrow palate; moderate mental retardation. A genetic defect of the fibroblast growth factor receptor, located on chromosome 4, is apparently responsible for about one-third of cases that are not associated with other deformities ([Moloney et al](#)).

2. *Median cleft facial syndrome (frontonasal dysplasia; hypertelorism of Greig)*. Widely spaced eyes, broad nasal root, cleft nose and premaxilla, V-shaped frontal hairline, heterotypic anterior frontal fontanel (midline cranial defect); mild to severe mental retardation.
3. *Chondrodystrophia calcificans congenita (chondrodysplasia punctata, Conradi-Hünerman syndrome)*. Prominent forehead; flat nose; widely separated eyes; short neck and trunk with kyphoscoliosis; dry, scaly, atrophic skin; cicatricial alopecia; irregularly deformed vertebral bodies; mental retardation infrequent. Severe shortening of limbs in some cases.
4. *Orofaciodigital syndrome*. All the patients are female. Pseudoclefts involving the mandible, tongue, maxilla, and palate; hypertrophied buccal frenuli; hamartomas of tongue; sparse scalp hair; subnormal intelligence in one-half of cases.
5. *Pyknodysostosis*. Large head and frontal-occipital bossing, underdeveloped facial bones, micrognathia, unerupted and deformed teeth, dense and defective long bones with shortened limbs, short and broad terminal digits of fingers and toes, mental retardation in one-quarter.
6. *Craniotubular bone dysplasias and hyperostoses*. Included under this title are several different genetic disorders of bone, characterized by modeling errors of tubular and cranial bones. Frontal and occipital hyperostosis, overgrowth of facial bones, and widening of long bones occur in various combinations. Hypertelorism, broad nasal root, nasal obstruction, seizures, visual failure, deafness, prognathism, and retardation of growth are the major features.

Oculoencephalic (Cranio-ocular) Defects In this category of anomalies, there is simultaneous failure or imperfect development of eye and brain. One member of this group, the oculocerebrorenal syndrome of Lowe, has already been mentioned on page 1002, and, of course, a number of the mucopolysaccharidoses are characterized by corneal opacities, skeletal changes, and psychomotor regression. Also, congenital syphilis, rubella, toxoplasmosis, and CMV inclusion disease may affect retina and brain; hypoxia at birth requiring treatment with oxygen may injure the brain and lead to *retrolental fibrodysplasia*.

1. *Anophthalmia with mental retardation*. Sex-linked recessive. Absent eyes; orbits and maxillae remain underdeveloped, but adnexal tissues of eyes (lids) are intact; subnormal intelligence.
2. *Norrie disease*. Also, sex-linked recessive; some sight may be present at birth; later, eyes become shrunken and recessed (phthisis bulbi); some have short digits, outbursts of anger, hallucinations, and possibly regression of psychomotor function.
3. *Oculocerebral syndrome with hypopigmentation*. Autosomal recessive with absence of pigment of hair and skin; small, cloudy, vascularized corneas and small globes (microphthalmia); marked mental retardation; athetotic movements of limbs.
4. *Microphthalmia with corneal opacities, eccentric pupils, spasticity, and severe mental retardation*.
5. *Aicardi syndrome with ocular abnormality*. Chorioretinopathy, retinal lacunae, staphyloma, coloboma of optic nerve, microphthalmos, mental retardation, infantile spasms and other forms of epilepsy, agenesis of corpus callosum, and cortical heterotopias. The “bat-wing” deformity of the third and lateral ventricles on MRI images and asynchronous burst-suppression discharges and sleep spindles are diagnostic. The condition is found only in females.
6. *Lissencephaly of the Walker-Warburg type*. Autosomal recessive inheritance. Ocular lesions are constant but variable (retinal dysplasia, microphthalmia, coloboma, cataracts, corneal opacities). There may be hydrocephalus, and by CT scans or MRI, the lack of cerebral sulci (lissencephaly) is disclosed. The abnormal eyes and orbits and absence of cerebellar vermis are diagnostic.
7. *Congenital tapetoretinal degeneration (Leber amaurosis)*. Visual loss from birth, moderate to severe mental retardation, and microcephaly. Early onset of blindness and absent electrical potentials on the electroretinogram (ERG) distinguish it from later-onset Leber optic atrophy.
8. *Septo-optic dysplasia (de Morsier syndrome)*. Diminished visual acuity, small optic discs, absence of septum pellucidum, and precocious puberty. Varying degrees of pituitary insufficiency may be present, requiring endocrine replacement.

Oculoauriculocephalic Anomalies These are less important from the neurologic standpoint and mental retardation is present only in some cases.

1. *Mandibulofacial dysostosis (Treacher-Collins syndrome, Franceschetti-Zwahlen-Klein syndrome)*.
2. *Oculoauriculovertebral dysplasia (Goldenhar syndrome)*.
3. *Oculomandibulodyscephaly with hypotrichosis (Hallermann-Streiff syndrome)*.

Dwarfism Midgets are abnormally small but perfectly formed people of normal intelligence; they differ from dwarfs, who are not only very small but whose bodily proportions are markedly abnormal. A majority of mentally retarded patients fall below average for height and weight, but there is a small group whose fully attained height is well below 135 cm (4 1/2 ft) and who stand apart by this quality alone (see [K. L. Jones](#) for Smith's classification of dwarfs).

1. *Nanocephalic dwarfism (Seckel bird-headed dwarfism)*. The uncomplimentary term *bird head* has been applied to individuals with a small head, large-appearing eyeballs, beaked nose, and underdeveloped chin. Such a physiognomy is not unique to any disease, but when combined with dwarfism it includes a few more or less specific syndromes. Up to 1976, approximately 25 cases had been reported, some with other skeletal and urogenital abnormalities, such as medial curvature of middle digits; occasional syndactyly of toes; dislocations of elbow, hip, and knee; premature closure of cranial sutures; and clubfoot deformity. These individuals are short at birth and remain so, living until adolescence or adulthood. Retardation is severe. A recessive autosomal type of inheritance is probable. At autopsy the brain is found to have a simplified convolutional pattern; one of our patients had a type of myelin degeneration similar to that of Pelizaeus-Merzbacher disease.
2. *Russell-Silver syndrome*. Possibly an autosomal dominant pattern of inheritance, with short stature of prenatal onset, craniofacial dysostosis, short arms, congenital hemihypertrophy (arm and leg on one side larger and longer), pseudohydrocephalic head (normal-sized cranium with small facial bones), abnormalities of genital development in one-third of cases, delay in closure of fontanels and in epiphyseal maturation, elevation of urinary gonadotropins.
3. *Smith-Lemli-Opitz syndrome*. Autosomal recessive inheritance with microcephaly, broad nasal tip and anteverted nares, wide-set eyes, epicanthal folds, ptosis, small chin, low-set ears, enlarged alveolar maxillary ridge, cutaneous syndactyly, hypospadias in boys, short stature, subnormal neonatal activity, normal amino acids and serum immunoglobulins. Older survivors are bereft of language and paraparetic, with increased reflexes and Babinski signs. The hips are usually dislocated. The karyotype is normal. The brain is small but has not been fully examined. Two of our patients are sibling girls.
4. *Rubinstein-Taybi syndrome*. Microcephaly but no craniostenosis, downward palpebral slant, heavy eyebrows, beaked nose with nasal septum extending below alae nasi, mild retrognathia, “grimacing smile,” strabismus, cataracts, obstruction of nasolacrimal canals, broad thumbs and toes, clinodactyly, overlapping digits, excessive hair growth, hypotonia, lax ligaments, stiff gait, seizures, hyperactive tendon reflexes, absence of corpus callosum, mental retardation, and short stature.
5. *Pierre Robin syndrome*. Possible autosomal recessive pattern of inheritance with microcephaly but no craniostenosis, small and symmetrically receded chin (“Andy Gump” appearance), glossoptosis (tongue falls back into pharynx), cleft palate, flat bridge of nose, low-set ears, mental deficiency, and congenital heart disease in half the cases. Camptomelia (bent bones), diastrophic dwarfism (short limbs) common.
6. *DeLange syndrome*. The phenotype shows some degree of variability, but the essential diagnostic features are intrauterine growth retardation and stature falling below the third percentile at all ages, microbrachycephaly, generalized hirsutism and eyebrows that meet across the midline (synophrys), anteverted nostrils, long upper lip, and skeletal abnormalities (flexion of elbows, webbing of second and third toes, clinodactyly of fifth fingers, transverse palmar crease). All are severely retarded mentally, which, with craniofacial abnormalities, is diagnostic. It has been said, and it has been our experience, that these patients are prone to have a bad disposition, manifest as by biting and spitting. There are no chromosomal abnormalities. A polygenic inheritance has been postulated, but most cases are sporadic.

Neurocutaneous Anomalies with Mental Retardation

It is not surprising that skin and nervous system should share in pathologic states that impair development, since both have a common ectodermal derivation. Nevertheless, it is difficult to find a common theme in the diseases that affect both organs. In some instances, it is clear that ectoderm has been malformed from early intrauterine life; in others, a number of acquired diseases of skin may have been superimposed. For reasons to be elaborated later, neurofibromatosis, tuberous sclerosis, and Sturge-Weber encephalofacial angiomatosis must be set apart as a different category of disease.

Hemangiomas of the skin are without doubt the most frequent cutaneous abnormalities present at birth, and usually they are entirely innocent. Many recede in the first months of life. On the other hand, an extensive vascular nevus located in the territory of the trigeminal nerve—and sometimes in other parts of the body as well—causes permanent disfigurement and usually portends an associated cerebral lesion.

Other neurocutaneous diseases are summarized below. A more complete review of these diseases will be found in the article by Short and Adams and the monograph edited by [Gomez](#), listed in the References. The related category of phakomatoses is discussed on pages 1069–1077. The importance of recognizing the cutaneous abnormalities relates to the fact that the nervous system is usually abnormal, and often the skin lesion appears before the neurologic symptoms are detectable. Thus

the skin lesion becomes a predictor of potential neurologic involvement.

1. *Basal-cell nevus syndrome*. This condition is transmitted as an autosomal dominant trait and is characterized by superficial pits in the palms and soles; multiple solid or cystic tumors over the head, face, and neck appearing in infancy or early childhood; mental retardation in some cases; frontoparietal bossing; hypertelorism; and kyphoscoliosis.
2. *Congenital ichthyosis, hypogonadism, and mental retardation*. This disorder is inherited as a sex-linked recessive trait. Aside from the characteristic triad of anomalies, there are no special features.
3. *Xeroderma pigmentosum*. The pattern of inheritance is autosomal recessive. Skin lesions appear in infancy, taking the form of erythema, blistering, scaling, scarring, and pigmentation on exposure to sunlight; old lesions are telangiectatic and parchment-like, covered with fine scales; skin cancer may develop later; loss of eyelashes, synblepharon, dry bulbar conjunctivae; microcephaly, hypogonadism, and mental retardation (50 percent of cases). Kanda and associates classify this disease with the DeSanctis-Cacchione syndrome of xerodermic idiocy and believe the basic mechanism to be a faulty repair of DNA. These authors described two young adults with low intelligence, evidence of spinal cord degeneration, and peripheral neuropathy. The peripheral nerve lesions resembled those of amyloidosis, Riley-Day syndrome, and Fabry disease in that there was a predominant loss of small fibers. Other variants are described.
4. *Sjögren-Larssen syndrome*. Autosomal recessive with congenital ichthyosiform erythroderma, normal or thin scalp hair, sometimes defective dental enamel, pigmentary degeneration of retinae, spastic legs, and mental retardation.
5. *Poikiloderma congenitale (Rothmund-Thompson syndrome)*. Autosomal recessive heredity; appearance of skin changes from the third to sixth months of life; diffuse pink coloration of cheeks spreading to ears and buttocks, later replaced by macular and reticular pattern of skin atrophy mixed with striae, telangiectasia, and pigmentation; sparse hair in half of the cases; cataracts; small genitalia; abnormal hands and feet; short stature; and mental retardation.
6. *Linear sebaceous nevus syndrome*. Genetics uncertain, linear organoid nevus of one side of face and trunk, lipodermoids on bulbar conjunctivae, vascularization of corneas, mental retardation, focal seizures, and spike and slow waves in the EEG.
7. *Incontinentia pigmenti (Bloch-Sulzberger syndrome)*. Only females affected; appearance of dermal lesions in first weeks of life; vesicles and bullae followed by hyperkeratoses and streaks of pigmentation, scarring of scalp, and alopecia; abnormalities of dentition; hemiparesis; quadriparesis; seizures; mental retardation; up to 50 percent eosinophils in blood. The status of this disease is uncertain.
8. *Focal dermal hypoplasia*. Also, a disease limited to females. Areas of dermal hypoplasia with protrusions of subcutaneous fat, hypo- and hyperpigmentation, scoliosis, syndactyly in a few, short stature, thin body habitus, intelligence occasionally subnormal.

Other rare entities are neurocutaneous melanosis, neuroectodermal melanolysosomal disease with mental retardation, progeria, Cockayne syndrome, ataxia telangiectasia ([Chap. 37](#); see also [Gomez](#)).

Dysraphism or Rachischisis (Encephaloceles and Spina Bifida)

Included under this heading are the large number of disorders of fusion of dorsal midline structures of the primitive neural tube, a process that takes place during the first 3 weeks of postconceptual life. Exogenous factors are presumed to be operative. The entire cranium may be missing at birth, and the undeveloped brain lies in the base of the skull, a small vascular mass without recognizable nervous structures. This state, *anencephaly*, has been discussed in the section “Disturbances of Neuronal Migration,” above, and is the most frequent of the rachischises. It has many associations with other conditions in which the vertebral laminae fail to fuse.

An eventration of brain tissue and its coverings through an unfused midline defect in the skull is called an *encephalocele*. Frontal encephaloceles may deform the forehead or remain occult. Associated defects of the frontal cortex, anterior corpus callosum, and optic-hypothalamic structures and CSF leakage into frontal or ethmoid sinuses pose a risk of meningitis. Some of these children are relatively normal mentally. Far more severe are the posterior encephaloceles, some of which are enormous and are attended by grave neurologic deficits. However, lesser degrees of the defect are well known and may be small or hidden, such as a *meningoencephalocele* connected with the rest of the brain through a small opening in the skull. Small nasal encephaloceles may cause no neurologic signs, but if they are mistaken for nasal polyps and snipped off, CSF fistulae may result. The larger occipital ones are associated with blindness, ataxia, and mental retardation.

A failure of development of the midline portion of the cerebellum, referred to earlier, forms the basis of the *Dandy-Walker syndrome* ([Fig. 38-2](#)). A cyst-like structure, representing the greatly dilated fourth ventricle, expands in the midline, causing the occipital bone to bulge posteriorly and to displace the tentorium and torcula upward. In addition, the cerebellar vermis is aplastic, the corpus callosum may be deficient or absent, and there is dilatation of the aqueduct as well as the third and lateral ventricles.

Figure 38-2 Dandy-Walker syndrome. MRI showing agenesis of the midline cerebellum and large midline cyst, representing the greatly dilated fourth ventricle, which occupies the posterior fossa. A. Axial view, B. Sagittal view.

Even more frequent are abnormalities of closure of the vertebral arches. These take the form of a *spina bifida occulta*, *meningocele*, and *meningomyelocele* of the lumbosacral or other regions.

In *spina bifida occulta*, the cord remains inside the canal and there is no external sac, although a subcutaneous lipoma or a dimple or wisp of hair on the overlying skin may mark the site of the lesion. In *meningocele*, there is a protrusion of only the dura and arachnoid through the defect in the vertebral laminae, forming a cystic swelling usually in the lumbosacral region; the cord remains in the canal, however. In *meningomyelocele*, which is 10 times as frequent as meningocele, the cord (more often the cauda equina) is extruded also and is closely applied to the fundus of the cystic swelling.

The incidence of spinal dysraphism (myeloschisis), like that of anencephaly, varies widely from one locale to another, and the disorder is more likely to occur in a second child if one child has already been affected (the incidence rises from 1 per 1000 to 40 to 50 per 1000). Exogenous factors (e.g., potato blight in Ireland) have been implicated in the genesis of both myeloschisis and anencephaly. Vitamin A and especially folic acid, given before the 28th day of pregnancy, can be protective. As with anencephaly, the diagnosis can often be inferred by the presence of α -fetoprotein in the amniotic fluid (sampled at 15 to 16 weeks of pregnancy) and the deformity confirmed by ultrasound in utero; blood contamination is a source of error in the fetoprotein test ([Milunsky](#)). Acetylcholinesterase immunoassay, done on amniotic fluid, is another reliable means of confirming the presence of neural tube defects. Some parents, on receiving this information, request abortion.

In the case of meningomyelocele, the child is born with a large externalized lumbosacral sac covered by delicate, weeping skin. It may have ruptured in utero or during birth, but more often the covering is intact. Stroking of the sac may elicit involuntary movements of the legs. As a rule the legs are motionless; urine dribbles, keeping the patient constantly wet; there is no response to pinprick over the lumbosacral zones; and the tendon reflexes are absent. In contrast, craniocervical structures are normal unless a Chiari malformation is associated (see further on). The neurologic abnormalities of the legs prove that the sac contains elements of spinal cord or cauda equina. Differences are noted in the neurologic picture depending on the level of the lesion. If it is entirely sacral, bladder and bowel sphincters are affected but legs escape; if lower lumbar and sacral, the buttocks, legs, and feet are more impaired than hip flexors and quadriceps; if upper lumbar, the feet and legs are sometimes spared and ankle reflexes retained, and there may be Babinski signs. The dreaded complications of these severe spinal defects are meningitis and progressive hydrocephalus from a Chiari malformation, which is often associated (see below). The subject of neural tube defects has recently been reviewed by [Botto](#) and colleagues.

Treatment Opinions as to proper management are not entirely settled. Excision and closure of the coverings of the meningocele in the first few days of life is advised if the objective is to prevent a fatal meningitis. After a few weeks or months, as hydrocephalus reveals its presence by rapid increase in head size and enlargement of the ventricles on the CT scan, a ventriculoatrial or ventriculoperitoneal shunt is required. Patients with high spinal lesions and total paraplegia, kyphosis, hydrocephalus, and other major congenital anomalies are usually not accepted for treatment. Less than 30 percent of such patients survive beyond 1 year, and the long-term results of treating these patients have not been encouraging. Lorber and others report that 80 to 90 percent of their surviving patients are mentally retarded to some degree and are paraplegic—thus totally dependent on others for their care. The decision to undertake rather formidable surgical procedures is being questioned more and more frequently. Exceptionally, the patient with meningocele and most of those with lumbar meningocele are mentally normal. Clinical differentiation of these two lesions is important.

Other Developmental Spinal Defects and Delayed Effects of Failure of Midline Fusion, Including Tethered Cord The problems of meningocele and its complications are so strictly pediatric and surgical that the neurologist seldom becomes involved except in the initial evaluation of the patient, in the treatment of meningeal infection, or in the case of shunt failure with decompensation of hydrocephalus. Of greater interest to the neurologist are a series of closely related abnormalities that produce symptoms for the first time in late childhood, adolescence, or even adult life. These include sinus tracts with recurrent meningeal infections, lumbosacral lipomas, and myeloschisis with low tethering of the spinal cord (“tethered cord”) and a delayed radicular or spinal cord syndrome; diastematomyelia, cysts, or tumors with spina bifida and a progressive myeloradiculopathy; and a Chiari malformation and syringomyelia that first present in adolescence or adult life. These abnormalities are described below.

Another class of disorders involves an occult lumbosacral dysraphism that is not inherited but is due to faulty development of the cell mass that lies caudal to the posterior neuropore (normally this undergoes closure by the 28th day of embryonic life). Occult spinal dysraphism of this type is also associated with meningoceles, lipomas, and sacrococcygeal teratomas. Another well-recognized anomaly is agenesis of the sacrum and sometimes the lower lumbar vertebrae (*caudal regression syndrome*). Interestingly, in 15 percent of such cases, the mother is diabetic ([Lyon and Evrard](#)). Here there is flaccid paralysis of legs, often with arthrogryptic contractures and urinary incontinence. Sensory loss is less prominent, mental function develops normally, and there is no hydrocephalus.

Sinus tracts in the lumbosacral or occipital regions are of importance, for they may be a source of bacterial meningitis at any age. They are often betrayed by a small dimple in the skin or by a tuft of hair along the posterior surface of the body in the midline. (The pilonidal sinus should not be included in this group.) The sinus tract may lead to a terminal myelocystocele and be associated with dermoid cysts or fibrolipomas in the central part of the tract. Cloacal defects (no abdominal wall and no partition between bladder and rectum) may be combined with anterior meningoceles. Evidence of sinus tracts should be sought in every instance of meningitis, especially when the infection has recurred.

There are, in addition, other *congenital cysts* and *tumors*, particularly lipoma and dermoid, that arise in the filum terminale and attach (tether) the cord to the sacrum; progressive symptoms and signs are produced as the spine elongates during development, stretching the caudally fixed cord ([Fig. 38-3](#)). Some of these children have bladder and leg weakness soon after birth. Others deteriorate neurologically at a later age (generally between 1.5 to 16 years, sometimes later). According to Chapman and Davis, it is not the myelolipoma but the tethering of the cord that gives rise to symptoms; removal of the tumor is of little benefit unless the cord is untethered at the same time. This may be difficult, for the lipoma may be fused with the dorsal surface of the spinal cord).

Figure 38-3 Magnetic resonance image of an adult with tethered cord and the typical lipoma at its caudal extent (arrow). The conus lies behind the lower lumbar vertebra. No dysraphism is present. The main features were a flaccid bladder, asymmetrical weakness and atrophy of the forelegs, and a degree of spasticity in the legs.

Diastematomyelia is another unusual abnormality of the spinal cord often associated with spina bifida. Here a bony spicule or fibrous band protrudes into the spinal canal from the body of one of the thoracic or upper lumbar vertebrae and divides the spinal cord in two halves for a variable vertical extent. Or the division of the cord may be complete, each half with its own dural sac and complete set of nerve roots. This longitudinal fissuring and doubling of the cord are spoken of as *diplomyelia*. With growth, it leads to a *traction myelopathy*, presenting with pain and progressive sensory, motor, and bladder symptoms, sometimes as late as adult life. Removal of the fibrous-bony spicule and untethering of the spinal cord have been beneficial in some cases.

Several clinical *syndromes of delayed progressive disease* (adolescents or adults), due mainly to a tethered cord, have been delineated:

1. *Progressive cauda equina syndrome* with lesions in the lumbosacral region. In our experience this has been the commonest presentation of the *tethered cord* syndrome, with or without a lipoma or dermoid. Complex disturbances of bladder function that produce urgency and incontinence beginning in the second or third decade may be the only manifestation, or the bladder symptoms may be combined with impotence (in the male) and numbness of the feet and legs or foot drop ([Pang and Wilberger](#)). Several of our adult patients have had unusual visceral reflex reactions, such as involuntary defecation or priapism with stimulation of the abdomen or perineum.
2. *Progressive spastic weakness* in some of the weak muscles of the legs in a patient known to have had a meningocele or meningocele. Presumably the spinal cord, which is securely attached to the lumbar vertebrae, is stretched during the period of rapid lengthening of the vertebral column.
3. *An acute cauda equina syndrome*, following some unusual activity or accident (e.g., rowing, or a fall in a sitting position), in patients who have had an asymptomatic or symptomatic spina bifida or meningocele. The implicated sensory and motor roots are believed to be injured by sudden or repeated stretching.
4. *Syringomyelia* (page 1337).

Also, there are a variety of neurologic problems associated with spinal abnormalities in the high cervical region [fusion of atlas and occiput or of cervical vertebrae (Klippel-Feil syndrome), congenital dislocation of the odontoid process and atlas, platybasia and basilar impression]. These abnormalities are reviewed in [Chap. 45](#), with other diseases of the spinal cord.

Chiari Malformation

Encompassed by this term are a number of congenital anomalies at the base of the brain, the most consistent of which are (1) extension of a tongue of cerebellar tissue, posterior to the medulla and spinal cord, into the cervical canal and (2) displacement of the medulla into the cervical canal, along with the inferior part of the fourth ventricle. These and associated anomalies were first clearly described by Chiari (1891, 1896). Arnold's name is often attached to the syndrome (Arnold-Chiari malformation), but his contribution to our understanding of these malformations was relatively insignificant. However, use of the double eponym is so entrenched that a dispute over its aptness will not alter its usage. Chiari recognized four types of abnormality. In recent years the term has come to be restricted to Chiari's types I and II—i.e., to the cerebellomedullary malformation without and with a meningocele, respectively. Type III Chiari malformation is no more than a high cervical or occipitocervical meningocele with cerebellar herniation, and type IV consists only of cerebellar hypoplasia.

Several other morphologic features are characteristic. The medulla and pons are elongated and the aqueduct is narrowed. The displaced tissue (medulla and cerebellum) occludes the foramen magnum; the remainder of the cerebellum, which is small, is also displaced so as to obliterate the cisterna magna. The foramina of Luschka and Magendie open into the cervical canal, and the arachnoidal tissue around the herniated brainstem and cerebellum is fibrotic. All these factors are

probably operative in the production of hydrocephalus, which is always associated. Just below the herniated tail of cerebellar tissue there is a kink or spur in the spinal cord, pushed posteriorly by the lower end of the fourth ventricle. In this type of malformation, a meningocele is nearly always found. It should also be emphasized that *hydromyelia* or *syringomyelia* of the cervical cord are commonly associated findings.

Developmental abnormalities of the cerebrum (particularly polymicrogyria) may coexist, and the lower end of the spinal cord (i.e., filum terminale) may extend as low as the sacrum. There are usually bony abnormalities as well. The posterior fossa is small; the foramen magnum is enlarged and grooved posteriorly. Nishikawa et al have suggested that smallness of the posterior fossa, with overcrowding, is the primary abnormality, leading to the brain malformation. Often the base of the skull is flattened or infolded by the cervical spine (basilar impression).

Clinical Manifestations In type II Chiari malformation (with meningocele), the problem is essentially one of progressive hydrocephalus. Cerebellar signs cannot be discerned in the first few months of life. However, lower cranial nerve abnormalities—laryngeal stridor, fasciculations of the tongue, sternomastoid paralysis (head lag), facial weakness, deafness, bilateral abducens palsies—may be present in varying combinations. If the patient survives to later childhood or adolescence, one of the syndromes that occurs with the type I malformation may become manifest.

In type I Chiari malformation (without meningocele or other signs of dysraphism), neurologic symptoms may not develop until adolescence or adult life. The symptoms may be those of (1) increased intracranial pressure, mainly headache, (2) progressive cerebellar ataxia, (3) progressive spastic quadriparesis, (4) downbeating nystagmus, or (5) syringomyelia (segmental amyotrophy and sensory loss, with or without pain). Or the patient may show a combination of disorders of the lower cranial nerves, cerebellum, medulla, and spinal cord (sensory and motor tract disorders), usually in conjunction with headache that is mainly occipital. This combination of symptoms is often mistaken for multiple sclerosis or a foramen magnum tumor. The symptoms may have an acute onset after sustained extension of the neck, as, for example, after a long session of dental work, hairdressing in women, or chiropractic manipulation. The physical habitus of such patients may be normal, but about 25 percent have signs of an arrested hydrocephalus or a short “bull neck.” When basilar impression and a Chiari malformation coexist, it may be impossible to decide which of the two is responsible for the clinical findings.

Diagnosis and Treatment Until the advent of MRI, myelography, performed with the patient supine, was the most reliable means of corroborating the clinical diagnosis. The tongue of cerebellar tissue and the kinked cervical cord obstructed the upward flow of dye and gave a highly characteristic radiologic profile. This procedure and several others have been superseded by MRI because of the clarity with which the latter exposes abnormalities of the craniocervical region ([Fig. 38-4](#)). Inspection of the axial sections of CT scans at the level of the foramen magnum also demonstrate crowding of the upper cervical canal by inferiorly displaced cerebellar tissue, but one must be aware of the variations in the normal position of the cerebellar tonsils at this level. The low-pressure CSF syndrome may also lead to a slight descent of the cerebellar tonsils that is reversible and is not indicative of a Chiari malformation. The CSF is usually normal but may show an elevated pressure and protein level in some cases.

Figure 38-4 Chiari type malformation and developmental syringomyelia. T1-weighted MRI the low-lying cerebellar tonsils below the foramen magnum and behind the upper cervical cord (upper arrow) and the syrinx cavity in the upper cord (lower arrow).

The treatment of Chiari malformation (and basilar impression) is far from satisfactory. If clinical progression is slight or uncertain, it is probably best to do nothing. If progression is certain and disability is increasing, upper cervical laminectomy and enlargement of the foramen magnum are indicated. Often this procedure halts the progress of the neurologic illness, arrests the hydrocephalus, or results in some improvement. The outcome, in our experience, has been unsatisfactory when decompression was performed mainly for intractable headache. The surgical procedure must be done cautiously. Opening of the dura and extensive manipulation of the malformation or excision of herniated cerebellum may aggravate the symptoms or even cause death. The treatment of an associated syringomyelia and other developmental abnormalities in this region is discussed further on page 1337.

Chromosomal Abnormalities (Chromosomal Dysgeneses)

A mid-twentieth-century discovery of outstanding significance was the recognition of a group of developmental anomalies of the brain and other organs associated with a demonstrable abnormality of an autosomal or sex chromosome. Jacobs and Lejeune almost simultaneously were the first to note a triplication of the twenty-first chromosome in the Down syndrome, and there followed the discovery of a number of other trisomies as well as deletions or translocations of other autosomal chromosomes and a lack or excess of one of the sex chromosomes. By recent count, 24 chromosomal abnormalities had been identified. Such an event must take place sometime after the formation of the oocyte, during the long period that it lies fallow in the aging ovary or during the process of conception or germination and first cell divisions. Thus, all the cells in the embryo may be affected or only some of them, the latter condition being called *mosaicism*.

The manner in which triplication or some other imperfection of a chromosome is able to derail the pathways of ontogenesis is a mystery. In some instances, a chromosomal imperfection may result from the lack of a gene or distortion or fragmentation of a gene or by an enlarged or unstable DNA nucleotide sequence, as in the fragile-X syndrome.

Certain chromosomal abnormalities are incompatible with life, and it has been found that the cells of many unexplained abortuses and stillborns show abnormal karyotypes. On the other hand, the organism may survive and exhibit any one of many syndromes, of which the following are the best known and most frequent: (1) Down syndrome (mongolism, trisomy 21); (2) one type of arrhinencephaly (trisomy 13, Patau syndrome); (3) trisomy 18 (Edwards syndrome); (4) cri-du-chat syndrome (deletion of short arm of chromosome 5); (5) monosomy 21 (antimongolism); (6) ring chromosomes; (7) Klinefelter syndrome (XXY); (8) Turner syndrome (XO); (9) others (XXXX, XXX, XYY, YY, XXYY); (10) the fragile-X syndrome, the most common form of inherited mental retardation; (11) Williams syndrome; (12) Prader-Willi and Angelman syndromes; and (13) Rett syndrome. The overall frequency of chromosomal abnormalities in live births is 0.6 percent ([Kalter and Warkany](#)). See [Lemieux](#) for a comprehensive account of the chromosome-linked disorders.

Down Syndrome Described first in 1866 by Langdon Down, this is the best known of the chromosomal dysgeneses. The frequency is 1 in 600 to 700 births, and this condition accounts for approximately 10 percent of all reported series of cases of severe mental retardation. Familiarity with the condition permits its recognition at birth, but it becomes more obvious with advancing age. The round head, open mouth, stubby hands, slanting palpebral fissures, and short stature impart an unmistakable clinical picture. The ears are low-set and oval, with small lobules. The palpebral fissures slant slightly upward and outward owing to the presence of medial epicanthal folds that partly cover the inner canthi (hence the old term “mongolism”). The bridge of the nose is poorly developed and the face is flattened (hypoplasia of the maxillae). The tongue is usually enlarged, heavily fissured, and protruded. Gray-white specks of depigmentation are seen in the irides (Brushfield spots). The little fingers are often short (hypoplastic middle phalanx) and incurved (clinodactyly). The fontanelles are patent but slow to close. The hands are broad, with a single transverse (simian) palmar crease and other characteristic dermal markings. Lenticular opacities and congenital heart lesions (septal and other defects) as well as gastrointestinal abnormalities (stenosis of duodenum) are frequent. Hypotonia of limbs is a prominent finding. At first the Moro response is reduced or absent, and feeding is difficult. The patient with Down syndrome is slightly below average size at birth and is characteristically short at later periods of life. The height attained in adult life seldom exceeds that of a 10-year-old child. Most affected children do not walk until 3 to 4 years of age; their acquisition of speech is delayed, but over 90 percent talk by 5 years. The intelligence quotient (IQ) is variable, and that of a large group follows a Gaussian curve; the median IQ is 40 to 50, and the range is 20 to 70. A placid, docile, and affectionate personality characterizes most Down patients. A high incidence of atlantoaxial instability puts them at risk of spinal cord compression in athletic ventures. Also, an increased incidence of myelocytic and lymphocytic leukemia takes its toll. A number of patients have had embolic strokes and brain abscesses secondary to cardiac abnormalities. Life expectancy is later shortened by the almost universal development of Alzheimer disease by the 40th

year of life.

One cannot distinguish the Down syndrome with a triplication of chromosome 21 from that with a translocation. There is a strong correlation between each of these types and the age of the mother. Whereas the triplication is found in the offspring of older mothers, the less frequent translocation is found equally in the offspring of young and old. In other subtypes of the Down syndrome, referred to as *mosaics*, some cells share in the chromosomal abnormality and others are normal. Mosaics have atypical forms of the syndrome, and some such individuals are of normal intelligence. Laboratory tests are not helpful in clarifying the mechanism of the disorder; abnormalities include decreased serotonin, increased alkaline phosphatase in the white cells, increased glucose diphosphate in red cells, and a 50 percent increase in superoxide dismutase. The latter enzyme derives from a gene located on the long arm of chromosome 21 and is a convenient marker of the trisomy, but it is not thought to be responsible for the dysmorphism or mental retardation. (This enzyme assumes importance in the familial form of amyotrophic lateral sclerosis.)

Pathologic Findings Brain weight is approximately 10 percent less than average. The convolutional pattern is rather simple. The frontal lobes are smaller than normal, and the superior temporal gyri are thin. There are claims of delayed myelination of cerebral white matter and also of immature and poorly differentiated cortical neurons. Alzheimer neurofibrillary changes and neuritic plaques are practically always found in Down cases beyond 40 years of age. As Alzheimer disease develops, the usual clinical picture is marked by inattentiveness, reduced speech, impairment of visuospatial orientation, loss of memory and judgment, and seizures.

It is possible to make the diagnosis of Down syndrome by demonstrating the chromosomal abnormalities in cells of the amniotic fluid. About one-third of pregnant mothers (in the second trimester) also have an abnormal elevation of serum a-fetoprotein. Other independent predictors of fetal Down syndrome are elevated serum chorionic gonadotropin and decreased estriol ([Haddow et al](#)). One can uncover a considerable proportion of the Down population by prenatal screening for these serum markers and doing amniocentesis on all pregnant women with positive tests to search for the chromosomal abnormality.

Other Chromosomal Dysgeneses

1. *Trisomy 13 (Patau syndrome)*. Frequency 1:2000 live births, more female than male, average maternal age 31 years, microcephaly and sloping forehead, microphthalmos, coloboma of iris, corneal opacities, anosmia, low-set ears, cleft lip and palate, capillary hemangiomata, polydactyly, flexed fingers, posterior prominence of heels, dextrocardia, umbilical hernia, impaired hearing, hypertonia, severe mental retardation, death in early childhood.
2. *Trisomy 18*. Frequency 1:4000 live births, more in females, average maternal age 34 years, slow growth, occasional seizures, severe mental retardation, hypertonia, ptosis and lid abnormalities, low-set ears, small mouth, mottled skin, clenched fists with index fingers over third finger, syndactyly, rocker-bottom feet, shortened big toe, ventricular septal defect, umbilical and inguinal hernias, short sternum, small pelvis, small mandible, death in early infancy.
3. *Cri-du-chat syndrome* (deletion in short arm of chromosome 5). Abnormal cry, like a kitten, severe mental retardation, hypertelorism, epicanthal folds, brachycephaly, moon face, antimongoloid slant of palpebral fissures, micrognathia, hypotonia, strabismus.
4. *Ring chromosomes*. Mental retardation with variable physical abnormalities.
5. *Klinefelter syndrome (XXY)*. Only males. Eunuchoid appearance, wide arm span, sparse facial and body hair, high-pitched voice, gynecomastia, small testicles, usually mentally retarded but not severely so; high incidence of psychosis, asthma, and diabetes.
6. *Turner syndrome (XO)*. Only females. Triangular face, small chin, occasionally hypertelorism and epicanthal folds, widely spaced nipples, clinodactyly, cubitus valgus, hypoplastic nails, short stature, webbed neck, delayed sexual development, mild mental retardation.
7. *Colpocephaly*. A rare type of malformation of the brain consisting of marked dilatation of the occipital horns of the lateral ventricles, thickening of the overlying rim of cortical gray matter, and thinning of the white matter. The associated clinical picture comprises mental retardation, spasticity, seizures, and visual abnormalities (due to optic nerve hypoplasia). This disorder is probably of diverse causation, but it is listed with the chromosomal abnormalities because some cases have been associated with the mosaicism for trisomy 8 ([Herskowitz et al](#)). The term colpocephaly is often used incorrectly to apply to all forms of ventricular enlargement associated with abnormal development of the brain.
8. *Fragile-X syndrome* (see also page 1097). With the advent of new markers for the detailed structure of chromosomes, Lubs observed an unusual site of frequent breakage (“fragility”) on the X chromosome and related it to a syndrome that includes mental retardation, flaring ears, elongated facies, slightly reduced cranial perimeter, normal stature, and enlarged testes. *This chromosomal abnormality appears to be the most common inherited form of mental retardation* (estimated to cause 1 case of retardation in every 1500 male births). Females, with their two X chromosomes, are affected about half as frequently, and then only to a slight degree. It is estimated that 10 percent of severely retarded males harbor the fragile-X chromosome. In the Fernald School population, this figure seems correct. The fragility appears to be due to a heritable, CGG-unstable repeating sequence. Affected individuals have over 200 repeats and normal carriers have 43 to 200 repeats. The prolonged sequence inactivates a gene (FMR1) that codes for an RNA-binding protein. Rousseau and colleagues have described a simple and sensitive test, using DNA analysis, for the diagnosis of the syndrome both prenatally and after birth. Because the length of the triplet repeat relates to the degree of expression of retardation, the fragile-X alteration occasionally turns up in mentally normal males, and in some instances the male children of their daughters have the disease. In some of our cases, the intellectual deficit has been moderate in degree; the main abnormalities have taken the form of troublesome behavior, logorrhea, an autistic type of gaze aversion, and asociality. These and other peculiar features of the syndrome and its unique pattern of inheritance (it is neither recessive nor dominant) have been discussed by [Shapiro](#). At first, it was assumed that the fragile-X syndrome was only an example of the Renpenning syndrome (hereditary feeble-mindedness in males with X-linked chromosomal disorder—see pages 635 and 1098), until it was pointed out that in this latter condition, stature was reduced, as was the cranial circumference, and that the X chromosomes of the Renpenning patients were not fragile.
9. *Williams syndrome*. Described by J. C. P. Williams of Australia from the perspective of a supravalvular aortic stenosis and later by [Beuren](#) and colleagues, this unique combination of cerebral maldevelopment and cardiovascular abnormalities has been traced in most patients to a microdeletion on chromosome 7 in the region of the gene that codes for elastin. Its frequency is 1:20,000 newborns. Further discussion of clinical features of this syndrome will be found on page 1098.
10. *Prader-Willi and Angelman syndromes*. The Prader-Willi syndrome has already been mentioned in relation to the hyperphagia of hypothalamic disorders (page 595). It is a not uncommon syndrome (one in 20,000 births) and affects both sexes equally. Hypotonia, areflexia, small stature, dysmorphic facies, and hypoplastic genitalia are evident and arthrogryposis may be present at birth; after the first year, mental retardation becomes obvious and obesity, due to hyperphagia, becomes prominent. Patients are identified by the H3O mnemonic, referring to hypomentia, hypotonia, hypogonadism, and obesity. The disorder is associated with a deletion at 15q11-q13, which can be identified by a combination of cytogenetic and DNA analyses. In 70 percent of cases the disease is due to a noninherited deletion from the paternal X chromosome. The Angelman syndrome, another cause of severe mental retardation, is associated with the identical chromosomal abnormality that is found in the Prader-Willi syndrome, i.e., a deletion at 15q11-q13, but in the case of Angelman syndrome there is usually a maternally inherited single gene defect. The difference in phenotype derives from a complex genetic phenomenon termed *spatially restricted imprinting*. Phenotypically, however, the two disorders are quite distinct. The Angelman syndrome, in addition to mental retardation, is characterized by microcephaly, the early development of seizures that are refractory to antiepileptic drugs, and an unusual marionette-like stance and movement disorder coupled with a persistent tendency to laugh and smile (hence the old name “happy puppet syndrome”).
11. *Rett syndrome*, discussed more fully on page 1098, is due to a dominant defect on the X chromosome. It affects one of every 10,000 to 15,000 girls. After 6 to 18 months of normal development, motor skills and mental abilities slowly regress. Certain hand-wringing and other stereotyped hand movements are characteristic as the disease progresses.

Several generalizations can be made about these chromosomal dysgeneses. First, the autosomal ones are often lethal, and they almost always have a devastating effect on cerebral growth and development, whether the infant survives or not. Anomalies of nonneural structures are regularly present—an association so constant that one may safely predict that a normally formed infant will not have a detectable chromosomal defect. However, only in the Down syndrome and trisomy 13 (and possibly trisomy 18) are the physiognomy and bodily configuration of predictive value. Surprisingly, some of the most grotesque disfigurements, such as anencephaly and multiple congenital anomalies, are not related to a morphologic abnormality of chromosomes. By contrast, an insufficiency of sex chromosomes does induce subtle effects on the brain, affecting intellect, and personality; to some extent this is true of supernumerary sex chromosomes (XYY, for example).

The basic abnormality of the brain underlying the mental retardation in many of these chromosomal dysgeneses has not been ascertained. The cerebra are slightly small, but only minor changes are seen in the convolutional pattern and cortical architecture in conventional microscopic preparations. Neurocellular methodologies are not sufficiently advanced to reveal the abnormalities.

Environmental Teratologic Factors

A number of observations have repudiated the belief that the human embryo is shielded against exogenous causes of maldevelopment. Irradiation during the first trimester, rubella and CMV infections, severe hypothyroidism of the mother during this same period, and the action of aminopterin, alcohol, vitamin A, and thalidomide all give rise to serious disorders of development. Also, the offspring of mothers receiving anticonvulsant drugs during the early months of pregnancy have a slightly increased risk of developing birth defects (approximately 5 percent, compared to 3 percent for the general population). The greatest risk is with trimethadione, but phenytoin, carbamazepine, valproate, and phenobarbital have also been implicated. Cleft lip and palate are the most common anomalies attributable to anticonvulsant drugs; other craniofacial defects, spina bifida, and dysraphisms have also been reported ([Janz et al](#)). Concerning other teratogens, there is much controversy. Claims and counterclaims have been made concerning the pathogenicity of the substances listed in [Table 38-2](#). Mainly, the data are from animals given amounts far in

excess of any possible therapeutic doses in humans. The data are so meager that they are not discussed here. The reader may refer to the article by [Kalter and Warkany](#) for further information.

THE PHAKOMATOSES (CONGENITAL ECTODERMOSSES)

As stated earlier, there are two broad categories of neurocutaneous diseases. In one, the infant is born with a special type of skin disease or develops it in the first weeks of life; in the other, particular forms of cutaneous abnormality, though often present in minor degree at birth, later evolve as quasi-neoplastic disorders. The latter, to which van der Hoeve (1920) applied the term *phakomatoses* (from the Greek *phakos*, meaning “mother spot,” “mole,” or “freckle”), include tuberous sclerosis, neurofibromatosis, and cutaneous angiomatosis with central nervous system (CNS) abnormalities. These diseases have many features in common—hereditary transmission, involvement of organs of ectodermal origin (nervous system, eyeball, retina, and skin), slow evolution of lesions in childhood and adolescence, tendency to form hamartomas (benign tumor-like formations due to maldevelopment), and a disposition to fatal malignant transformation. These disorders are discussed below.

Tuberous Sclerosis (Bourneville Disease)

Tuberous sclerosis is a congenital disease of hereditary type in which a variety of lesions, due to a limited hyperplasia of ectodermal and mesodermal cells, appear in the skin, nervous system, heart, kidney, and other organs. It is characterized clinically by the triad of adenoma sebaceum, epilepsy, and mental retardation.

It is stated that Virchow had recognized scleromas of the cerebrum in the 1860s and that von Recklinghausen had reported a similar lesion combined with multiple myomata of the heart in 1862, but Bourneville’s articles, appearing between 1880 and 1900, presented the first systematic accounts of the disease and related the cerebral lesions to those of the skin of the face. Vogt (1890) fully appreciated the significance of the neurocutaneous relationship and formally delineated the triad of *facial adenoma sebaceum, epilepsy, and mental retardation*. “Epiloia,” a term for the disease introduced by Sherlock in 1911, never gained general acceptance. These and other historical aspects are reviewed in Gomez’s monograph on tuberous sclerosis.

Epidemiology This disease has been described in all parts of the world and is equally frequent in all races and both sexes. Heredity is evident in only a minority of cases—50 percent in some series and as little as 14 percent in the series of Bundag and Evans (cited by [Brett](#)). It is determined by a single autosomal dominant gene, the estimated prevalence of which is 1:50,000 to 1:300,000. The remaining cases are attributed to a gene mutation, the frequency of which is calculated to be 1:20,000 to 1:50,000. The disease involves many organs in addition to the skin and brain, and it may assume a diversity of forms, the least severe of which (i.e., the forme fruste) is difficult to diagnose; hence, one cannot be precise about the incidence of the disease. Tuberous sclerosis accounts for about 0.66 percent of the mentally retarded in institutions and 0.32 percent of epileptics. The medical literature contains a number of reports of patients whose mentality is preserved and who have never had convulsions. It is likely that data drawn from mental hospital populations have exaggerated the overall frequency of mental retardation ([Gomez](#)).

Etiology and Pathogenesis The abnormal gene has been localized to one of two sites—the long arm of chromosome 9, designated as TSC 1, and the short arm of chromosome 16, TSC 2. The former site is linked closely to the ABO blood group genes. The mutations are at loci of tumor-suppressor genes that are inactivated and this may, in part, explain the proclivity to develop various growths and hamartomas. Several hypotheses relating to neuronal migration or to the excessive secretion of growth factors have been proposed to link the inactivation of these genes with the pathogenesis of the characteristic lesions. The cellular elements within the lesions are abnormal in both number and size. The tumor-like growths in different organs may include cells of more than one type (e.g., fibroblasts, cardiac myoblasts, angioblasts, glioblasts, and neuroblasts), and their number is locally excessive. Something appears to have gone awry with the proliferative process during embryologic development, yet it is usually kept under control, in the sense that only rarely do the growths undergo malignant transformation. Highly specialized cells within the lesions may attain giant size; neurons three to four times normal size may be observed in the cerebral scleroses. These facts emphasize the potentially blastomatous character of the process.

Clinical Manifestations The disease may be present at the time of birth (the diagnosis has been made by CT scan in neonates), but more often the infant is judged at first to be normal. In approximately 75 percent of cases, attention is drawn to the disease initially by the occurrence of focal or generalized seizures or by retarded psychomotor development. As with any condition that leads to mental retardation, the first suspicion is raised by delay in reaching normal maturational milestones. Whatever the initial symptom, the convulsive disorder and mental retardation become more prominent within 2 to 3 years. The facial cutaneous abnormality, the so-called adenoma sebaceum, appears later in childhood, usually between the fourth and tenth years, and is progressive thereafter.

As the years pass, the seizures change pattern. In the first year or two they take the form of massive flexion spasms with hypsarrhythmia (irregular dysrhythmic bursts of high-voltage spikes and slow waves in the EEG). As many as 25 percent of our patients with these types of seizures have been found to have tuberous sclerosis. Later, the seizures change to more typical generalized motor and psychomotor attacks or atypical petit mal. Any one of the seizure types may be brief, especially if the patient is receiving anticonvulsant medication. Seizures are always the most reliable index of the cerebral lesions; focal neurologic abnormalities, which one might expect to occur from the size and location of the lesions, are distinctly uncommon.

Mental function continues to deteriorate slowly. Exceptionally there is a spastic weakness or mild choreoathetosis of the limbs and in a few cases an obstructive hydrocephalus. As in any state of severe mental retardation, a variety of nonspecific motor peculiarities—such as constant crying, muttering, stereotypical rocking and swaying movements, and digital mannerisms—may be observed. In nearly half of the cases, affective and behavioral derangements, often of hyperkinetic and aggressive type, are added to the intellectual deficiency.

The lack of parallelism in the severity of the epilepsy, mental deficit, and cutaneous abnormalities has been noted by all clinicians who have had a wide experience with this disease. Some patients are subject to recurrent seizures while retaining relatively normal mental function; in others, trivial skin lesions or a retinal phakoma may suggest the diagnosis in a mentally normal person with few seizures. In such cases, recognition may elude competent neurologists and dermatologists. As a general rule, early onset of seizures is predictive of mental retardation. Gomez and colleagues have suggested that the seizures damage the brain, a point with which we agree. However, it seems likely that both the epilepsy and mental retardation are the product of severe involvement of the brain by the lesions of tuberous sclerosis.

Limitation of space allows no more than a catalogue of other visceral abnormalities. In about half the cases, gray or yellow plaques (in reality gliomatous tumors) may be found in the retina in or near the optic disc or at a distance from it. It is from this lesion, called a *phakoma*, that van der Hoeve derived the term that is applied to all neurocutaneous diseases of this class. About half of all benign rhabdomyomas of the heart are associated with tuberous sclerosis, and, if located in the wall of the atrium, they may cause conduction defects. Other benign tumors of mixed cell type (angiomyolipomas) have been found in the kidneys, liver, lungs, thyroid, testes, and gastrointestinal tract. Cysts of the pleura or lungs, bone cysts in digits, and zones of marbling or densification in bones are some of the less common abnormalities.

In approximately 90 percent of patients with tuberous sclerosis, congenital hypomelanotic macules (formerly mistaken for “partial albinism” or “vitiligo”) appear before

any of the other skin lesions ([Fitzpatrick et al](#)). They are arranged in linear fashion over the trunk or limbs and range in size from a few millimeters to several centimeters; their configuration is oval, with one end round and the other pointed, in the shape of an ash leaf. A Wood's lamp, which transmits only ultraviolet rays, facilitates the demonstration of the ash leaf lesions because of the absence of melanoblasts, which normally absorb light in the ultraviolet range (360-nm wavelength). These lesions become pink when rubbed and contain sweat glands; they are not usually present on the face or head. There is occasionally a white tuft of hair (poliosis). Electron microscopic examination shows a normal or reduced number of melanocytes, but their dopa reaction is reduced and melanosomes are small. Gold and Freeman as well as Fitzpatrick and colleagues have emphasized the frequency of these leukodermic lesions and their value in the diagnosis of tuberous sclerosis during infancy, before the appearance of other cutaneous lesions.

The well-developed facial lesions (adenomas of Pringle), pathognomonic of tuberous sclerosis, are present in 90 percent of patients over 4 years of age. Typically they are red to pink nodules with a smooth, glistening surface, and they tend to be limited to the nasolabial folds, cheeks, and chin; sometimes they also involve the forehead and scalp. Although called “adenoma sebaceum,” these nodules are actually angiofibromas; the sebaceous glands are only passively involved ([Fig. 38-5](#)). The earliest manifestation of facial angiofibromatosis may be a mild erythema over the cheeks and forehead, intensified by crying. The occurrence of large plaques of connective tissue on the forehead is usually expressive of a severe form of the disease.

Figure 38-5 *Adenoma sebaceum of tuberous sclerosis.*

On the trunk, the diagnostic lesion is the “shagreen patch” (in reality a plaque of subepidermal fibrosis) found most often in the lumbosacral region. It appears as a flat, slightly elevated, flesh-colored area of skin 1 to 10 cm in diameter, with a “pigskin,” “elephant hide,” or “orange peel” appearance ([Fig. 38-6](#)). Another common site of fibromatous involvement is the nail bed; subungual fibromas usually appear at puberty and continue to develop with age. Other common skin changes, not in themselves diagnostic, include fibroepithelial tags (soft fibromas), café au lait spots, and port-wine hemangiomas.

Figure 38-6 *Shagreen patch on the skin of the lower back in a young patient with tuberous sclerosis.*

Pathology The brain exhibits a number of diagnostic anomalies. Broadening, unnatural whiteness, and firmness of parts of some of the cerebral convolutions are simulated by no other disease. These are the tubers after which the disease is named. On the surface of the brain, they range in width from 5 mm to 2 or 3 cm. Their cut surface reveals a lack of demarcation from cortex and white matter and the presence of white flecks of calcium; the latter, which are readily seen on CT scans and MRI, are called *brain stones* (see below). The walls of the lateral ventricles may be encrusted with white or pink-white masses resembling candle gutterings. When calcified, they appear in radiographs as curvilinear opacities that follow the outline of the ventricle. Rarely, nodules of abnormal tissue are observed in the basal ganglia, thalamus, cerebellum, brainstem, and spinal cord.

Under the microscope the tubers are seen to be composed of interlacing rows of plump, fibrous astrocytes (much like an astrocytoma, though lacking in glial fibrillar protein). In the cerebral cortex and ganglionic structures, derangements of architecture result from the presence of abnormal-appearing cells; greatly enlarged “monstrous” neurons and glial cells—often difficult to distinguish from one another, and displaced normal-sized neurons contribute to the chaotic histologic appearance. Gliomatous deposits may obstruct the foramina of Monro or the aqueduct or floor of the fourth ventricle, causing hydrocephalus. Neoplastic transformation of abnormal glial cells, a not infrequent occurrence, usually takes the form of a large-cell astrocytoma, less often of a glioblastoma or meningioma.

The phakomas of the retina are composed mainly of neuronal and glial components, but occasionally there is an admixture of fibrous tissue.

Diagnosis When the full combination of seizures and mental and dermal abnormalities are conjoined, the diagnosis is self-evident. It is the early stage of the disease and the *forme fruste* that give trouble, and here the experienced dermatologist can be of great help. Epilepsy—i.e., flexion spasms in infancy—and delay in psychomotor development are by no means diagnostic of tuberous sclerosis, since they occur in many diseases. It is in these cases and also in every sizable population of the epileptic or mentally retarded, especially when the family history is unrevealing, that a search for the dermal equivalents of the disease—the hypomelanotic ash-leaf spots, adenoma sebaceum, collagenous patch, phakoma of the retina, or subungual or gingival fibromas—is so rewarding. The finding of any one of these lesions provides confirmation of the partial and atypical case. Adenoma sebaceum may occasionally occur alone and is easily confused with acne vulgaris in the adolescent. The history of epilepsy and/or the demonstration of a dull mentality are helpful, but neither is a requisite for the diagnosis of tuberous sclerosis ([Gomez](#)).

The most useful laboratory measures for corroborating the disease are CT scanning and MRI ([Fig. 38-7](#)). The periventricular calcific lesions are particularly well shown on the CT scan, whereas MRI is more sensitive in detecting cortical lesions. A striking feature is an absence of edema in the surrounding tissue. An increasing number of cortical lesions demonstrated with MRI appears to correlate with an increased impairment of neurologic function ([Roach et al](#)).

Figure 38-7 *Tuberous sclerosis. Subependymal nodules (“brain stones”) are demonstrated on both MRI (left) and CT (right).*

Treatment Nothing can be offered in the way of prevention other than genetic counseling. Anticonvulsant therapy of the standard type suppresses the convulsive tendency more or less effectively and should be applied assiduously. Adrenocorticotrophic hormone (ACTH) suppresses the flexor spasms and tends to normalize the EEG abnormality. It is pointless to attempt the excision of tumors, especially in severely affected individuals (with the exception of renal hamartomas that impair function). However, there are patients who are not mentally impaired and who have benefited from dermabrasion of the facial lesions, with the knowledge that these slowly regrow; and neurosurgeons have partially excised brain tumors that were causing recalcitrant epilepsy or shunted the lateral ventricular in patients with increased intracranial pressure.

Course and Prognosis In general, the disease advances so slowly that years must elapse before one can be sure of progression. Of the severe cases, approximately 30 percent die before the fifth year, and 50 to 75 percent before attaining adult age. Worsening is mainly in the mental sphere. Status epilepticus accounted for many deaths in the past, but improved anticonvulsant therapy has reduced this hazard. Neoplasias take their toll; the authors have had several such patients who died of malignant gliomas arising in striatohalamic regions.

Neurofibromatosis of von Recklinghausen

Neurofibromatosis (NF) is a comparatively common hereditary disease in which the skin, nervous system, bones, endocrine glands, and sometimes other organs are the sites of a variety of congenital abnormalities, often taking the form of benign tumors. The typical clinical picture, usually identifiable at a glance, consists of multiple circumscribed areas of increased skin pigmentation accompanied by dermal and neural tumors of various types.

The condition known as multiple idiopathic neuromas was the subject of a monograph by R. W. Smith in 1849; even at that time, he referred to examples recorded by other writers. It was von Recklinghausen, however, who in 1882 gave the definitive account of its clinical and pathologic features. The subsequent studies of the disease by [Yakovlev and Guthrie](#), [Lichtenstein](#), [Riccardi](#), and [Martuza and Eldridge](#), and most recently by [Créange et al](#) and the comprehensive monographs of Crowe and Riccardi and their colleagues have provided a complete analysis of the clinical, pathologic, and genetic data pertaining to the disease.

Epidemiology Crowe and associates have calculated the prevalence of the disease to be 30 to 40 per 100,000 and expect one case in every 2500 to 3300 births. Approximately half of their cases had affected relatives, and in all instances the distribution of cases within a family was consistent with an autosomal dominant mode of inheritance. The disease has been observed in all races in different parts of the world, and males and females are about equally affected.

Cause and Pathogenesis The hereditary nature of NF has been appreciated for many years. More recently it has been established that NF comprises two distinct disorders, the genes for which are located on two separate chromosomes. The classic form of the disease, described below, has been shown by linkage analysis to be caused by a mutation located near the centromere on chromosome 17 ([Barker et al](#)). The second type, in which the main feature is bilateral acoustic nerve neuromas, described further on, has been linked to a DNA marker on chromosome 22 ([Rouleau et al](#)). These two forms of NF have been loosely referred to as peripheral and central, respectively, but the terms *neurofibromatosis type 1* and *neurofibromatosis type 2* are less confusing ([Martuza and Eldridge](#)) and are used in the following discussion.

The pathogenesis remains obscure. Cellular elements derived from the neural crest (i.e., Schwann cells, melanocytes, and endoneurial fibroblasts, the natural components of skin and nerves) proliferate excessively in multiple foci, and the melanocytes function abnormally; but the hormones and growth factors that are involved in this proliferative process and the mechanism(s) by which it is accomplished are as unclear as in tuberous sclerosis.

Neurofibromatosis Type 1 (Classic, or Peripheral, NF) In the majority of patients, spots of hyperpigmentation and cutaneous and subcutaneous neurofibromatous tumors are the basis of clinical diagnosis. Pigmentary changes in the skin are nearly always present at birth, but neurofibromas are infrequent at that age. Both lesions increase in number and size during late childhood and adolescence. There may be a spurt of new lesions at puberty or during pregnancy. Exceptionally, a neurofibroma of a cranial nerve or a spinal root (sometimes with compression of the cord), disclosed during neurosurgical intervention, may be the initial manifestation of the disease. In the study of a large series of patients with neurofibromatosis ([Crowe et al](#)), approximately one-third were found to have the cutaneous manifestations while being examined for symptoms of some other disease; that is to say, the NF was asymptomatic. Usually these are the cases with the slightest degree of cutaneous abnormality. Of the remaining two-thirds, most consulted a physician because of the disfigurement produced by the tumors or because some of the neurofibromas were producing symptoms.

The patches of cutaneous pigmentation, appearing shortly after birth and occurring any place on the body, constitute the most striking clinical expression of the disease. They vary in size from a millimeter or two to many centimeters and in color from a light to dark brown (café au lait) and are rarely associated with any other pathologic state ([Fig. 38-8](#)). They do not appear to change in number as the patient ages but they do become more pigmented. In a survey of pigmented spots in the skin, Crowe and associates found that 10 percent of the normal population had one or more spots of this type; however, anyone with more than six such spots, some exceeding 1.5 cm in diameter, nearly always proved to have von Recklinghausen disease. Of their 223 patients with NF, 95 percent had at least one spot, and 78 percent had more than six large ones. Freckle-like or diffuse pigmentation of the axillae and other intertriginous areas (groin, under breast), and small, round, whitish spots are characteristic and almost pathognomonic of the syndrome.

Figure 38-8 *Typical large café au lait spot. The presence of six or more hyperpigmented lesions, each over 1.5 cm, is diagnostic of neurofibromatosis type 1.*

The appearance of multiple cutaneous and subcutaneous tumors in late childhood or early adolescence is the other principal feature of the disease. The cutaneous tumors are situated in the dermis and form discrete, soft or firm papules varying in size from a few millimeters to a centimeter or more (molluscum fibrosum; [Fig. 38-9](#)). They assume many shapes—flattened, sessile, pedunculated, conical, lobulated, and so on. They are flesh-colored or violaceous and often topped with a comedo.

When pressed, the soft tumors tend to invaginate through a small opening in the skin, giving the feeling of a seedless raisin or a scrotum without a testicle. This phenomenon, spoken of as “buttonholing,” is useful in distinguishing the lesions of this disease from other tumors, e.g., multiple lipomas. A patient may have anywhere from a few of these dermal tumors to hundreds. The subcutaneous neural tumors, which are also multiple, take two forms: (1) firm, discrete nodules attached to a nerve or (2) an overgrowth of subcutaneous tissue, sometimes reaching enormous size. The latter, which are called *plexiform neuromas* (also pachydermatocele, elephantiasis neuromatosis, *la tumeur royale*), occur most often in the face, scalp, neck, and chest and may cause hideous disfigurement. When palpated, they feel like a bag of worms or strings; the bone underlying the tumor may thicken. Neurofibromas are easily distinguished from lipomas, which are soft, unattached to the skin or nerve, and not accompanied by any neurologic disorder. The only exceptions to this statement are rare cases of multiple symmetrical lipomatosis with axonal polyneuropathy (Launois-Beusaude disease). As a rule, congenital neurofibromas tend to be highly vascular and invasive and are especially prominent in the orbital, periorbital, and cervical regions. They are often accompanied by hypertrophy of a segment of the body. When the hyperpigmentation overlies a plexiform neurofibroma and extends to the midline, one should suspect an intraspinal tumor at that level.

Figure 38-9 *Molluscum fibrosum non-neural skin tumors of von Recklinghausen disease.*

Other abnormalities associated with type 1 (peripheral) NF include bone cysts, pathologic fractures (pseudoarthrosis), cranial bone defects with pulsating exophthalmos (sphenoid bone dysgenesis), bone hypertrophy, precocious puberty, pheochromocytoma, scoliosis, syringomyelia, nodules of abnormal glial cells in brain and spinal cord, and macrocephaly, rarely with obstructive hydrocephalus due to overgrowth of glial tissue around the sylvian aqueduct and fourth ventricle. Some degree of intellectual impairment is common (40 percent of Riccardi's series of 133 patients); but in our experience the figure is much less, and the impairment is usually not profound. Learning difficulty, developmental disorder, or hyperactivity have been more frequent abnormalities, occurring in almost 40 percent of patients. Rosman and Pearce have ascribed mental retardation in NF to congenital malformation of the cerebral cortex (cortical dysgenesis). The incidence of seizures is about 20 times higher than that in the general population. Headache, hydrocephalus, and tumors involving the optic pathways, meningiomas, gliomas, and malignant peripheral nerve tumors are common, even among adults, according to the survey of 158 patients by [Créange](#) and colleagues; also, pain was a common symptom in adults and often related to a malignant peripheral nerve sheath tumor.

Another unique finding is the Lisch nodule. This is a small whitish spot (hamartoma) in the iris ([Fig. 38-10](#)), present in 94 percent of Riccardi's type 1 cases but not found in patients with type 2 NF (bilateral acoustic neuromas) or in normal individuals (see below). Exceptionally, NF has been associated with peroneal muscular atrophy, congenital deafness, and partial albinism ([Bradley et al](#)).

Figure 38-10 *Hamartomas of the iris (Lisch nodules), typical of neurofibromatosis, type 1.*

In childhood, progressive blindness is a particularly troublesome complication. One or both optic nerves are involved in a tumor mass composed mainly of astrocytes. The diagnosis comes to mind at once in a child with any of the cutaneous manifestations of NF. Uncertainty as to its nature arises from the fact that the neuropathologist may be unable to decide between a benign hamartoma and a grade 1 astrocytoma. Enlargement in a succession of MRI scans may be needed to affirm its blastomatous nature.

Neurofibromatosis Type 2 (Acoustic, or Central, NF) In type 2 neurofibromatosis, as mentioned above, there is an absence or paucity of cutaneous lesions. Progressive deafness and the demonstration by enhanced CT or MRI of *bilateral acoustic neuromas* affords accurate diagnosis ([Fig. 31-16](#)). Other cranial or spinal neurofibromas, meningioma (sometimes multiple), and glioma may be added to the syndrome of deafness. This condition is considerably less frequent than type 1 NF.

Pathology of NF1 and NF2 The cutaneous tumors are characterized by a rather thin epidermis whose basal layer may or may not be pigmented. The collagen and elastin of the dermis is replaced by a loose arrangement of elongated connective tissue cells. It lacks the compactness of the normal dermal collagen, which accounts for the palpable opening in the skin.

The pigmented (café au lait) lesions contain only the normal numbers of melanocytes; the dark color of the skin is due instead to an excess of melanosomes in the malpighian cells. Abnormally large melanosomes, measuring up to several microns in diameter, appear in some of the basal cells of the epidermis.

The nerve tumors are composed of a mixture of fibroblasts and Schwann cells (except the optic nerve tumors, which contain a combination of astrocytes and fibroblasts). Predominance of one or the other of these cells is the basis of the diagnosis of neurofibroma or schwannoma. Palisading of nuclei, sometimes encircling arrangements (Verocay bodies), is a feature of both. Occasionally, along spinal roots or sympathetic chains, one may find a tumor made up of partially or completely differentiated nerve cells (a typical ganglioneuroma). Clusters of abnormal glial cells may be found in the brain and spinal cord, and, according to Bielschowsky, they form a link with tuberous sclerosis. Clinically and genetically, however, the two diseases are quite independent.

Malignant degeneration of the tumors is found in 2 to 5 percent of cases; peripherally they become sarcomas, and centrally, astrocytomas or glioblastomas ([Fig. 38-11](#)).

Figure 38-11 Neurofibromatosis, type 1. T1-weighted MR image in the sagittal plane demonstrating a glioma involving the optic chiasm and brainstem (above). T2-weighted axial image showing multiple foci of hyperintensity, presumably hamartomas (below).

Diagnosis If skin tumors and café au lait spots are numerous and Lisch nodules are present in the iris, the identification of the disease as type 1 neurofibromatosis offers no difficulty. A history of the illness in antecedent and collateral family members makes diagnosis even more certain. Uncertainty arises most frequently in patients with bilateral acoustic neuromas or other cranial or spinal neurofibromas or schwannomas with no skin lesions or only a few random ones although the tendency for these forms of NF to be accompanied by a paucity of skin lesions is well recognized. Plexiform neuromas with muscle weakness, due to nerve involvement, and abnormalities of underlying bone may be confused with other tumors, especially in young children, who tend to have few café au lait spots and few cutaneous tumors. Hypertrophy of a limb, which may also occur, requires differentiation from other developmental anomalies.

As already mentioned, Crowe and coworkers believe that 80 percent of patients with von Recklinghausen disease can be diagnosed by the presence of more than six café au lait spots. Of the remaining 20 percent, those over 21 years of age will be found to have multiple cutaneous tumors, axillary freckling, and a few pigmented spots; in those under 21 with no dermal tumors and only a few café au lait patches, a positive family history and radiographic demonstration of bone cysts will be helpful in some instances. Café au lait spots and cutaneous tumors should always be sought, for they may help the neurologist diagnose an otherwise obscure progressive spinal syndrome, a cerebellopontine angle syndrome, bilateral deafness, progressive blindness, and an occasional case of precocious puberty, hydrocephalus, or mental retardation.

Because of the many conditions that accompany classic neurofibromatosis and because they are potentially dangerous, the initial clinical evaluation should be supplemented by a number of ancillary examinations: measurement of IQ, EEG, slit-lamp examination of irides, radiography of optic foramina and internal auditory meati, visual and auditory evoked responses, and CT scans or MRI of cranium and sometimes of spine and mediastinum. In the series of Duffner and colleagues, 74 percent of cases had abnormal signals in T2-weighted images of the basal ganglia, thalamus, hypothalamus, brainstem, and cerebellum. The EEG in their cases was abnormal in 25 percent. If there is suspicion of a pheochromocytoma, a 24-h urine should be tested for metabolites of epinephrine. Each of these tests not only is an aid to diagnosis but is essential to the intelligent management of the illness.

Treatment The skin tumors should not be excised unless they are cosmetically objectionable or show an increase in size, suggesting malignant change. The effects of radiotherapy are so insignificant that they do not justify the risk of exposure. Plexiform neuromas about the face offer especially difficult problems. Here one must resort to plastic surgery, but the results are not always satisfactory because the growths may involve cranial nerves superficially (with risk of greater paralysis after surgical excision) or alter the underlying bone, the latter being either eroded from pressure or hypertrophied from increased blood supply. Cranial and spinal neurofibromas are amenable to excision, and the gliomas and meningiomas usually demand surgical measures as well. Here the differentiation of hamartomas from gliomas of structures such as the optic nerves, hypothalamus, or pons may be difficult. Bilateral optic nerve gliomas are usually treated with radiation; unilateral ones are excised. Peripheral nerve tumors that have undergone malignant (sarcomatous) degeneration pose special surgical problems.

Affected individuals should be advised not to have children—a precaution that may not be necessary, because fertility, especially in males, seems to be reduced by the disease. Prognosis varies with the grade of severity, being most favorable in those with only a few lesions. But the disease is always progressive, and the patient should remain under continuous surveillance.

Cutaneous Angiomatosis with Abnormalities of the Central Nervous System

There are seven diseases in which a cutaneous or ocular vascular anomaly is associated with an abnormality of the nervous system: (1) meningo- or encephalofacial (encephalotrigeminal) angiomatosis with cerebral calcification (Sturge-Weber syndrome); (2) dermatomal hemangiomas and spinal vascular malformations (sometimes with limb hypertrophy, as in Klippel-Trenaunay-Weber syndrome); (3) the epidermal nevus (linear sebaceous nevus) syndrome; (4) familial telangiectasia (Osler-Rendu-Weber disease); (5) hemangioblastoma of cerebellum and retina (von Hippel-Lindau disease); (6) ataxia-telangiectasia (Louis-Bar disease); and (7) angiokeratosis corporis diffusum (Fabry disease). The last three disorders are considered elsewhere: ataxia-telangiectasia and Fabry disease with the inherited metabolic disorders (pages 1011 and 1037, respectively) and von Hippel-Lindau disease with intracranial neoplasms (page 705).

Meningo- or Encephalofacial Angiomatosis with Cerebral Calcification (Sturge-Weber Syndrome) A vascular nevus is observed at birth to cover a large part of the face and cranium on one side (in the territory of the ophthalmic division of the trigeminal nerve). In one-quarter of the cases the nevus is bilateral. The lesions vary in extent, the most limited being an involvement of only the upper eyelid and forehead and the most extensive being the entire head and even other parts of the body. The nevus is deep red (port-wine nevus), and its margins may be raised or flat; soft or firm papules, evidently composed of vessels, cause surface elevations and irregularities. Orbital tissue, especially the upper eyelid, is almost invariably involved; congenital buphthalmos may enlarge the eye before birth and glaucoma may develop later in that eye, causing blindness. The choroid is implicated in some cases. The increased cutaneous vascularity may result in an overgrowth of connective tissue and underlying bone, giving rise to a deformity like that of the Klippel-Trenaunay-Weber syndrome. Indications of cerebral affection appear as early as the first year of life or later in childhood; the most frequent clinical manifestations are unilateral seizures followed by increasing degrees of spastic hemiparesis with smallness of the arm and leg, hemisensory defect, and homonymous hemianopia, all on the side contralateral to the trigeminal nevus. Skull films (usually normal just after birth) taken after the second year reveal a characteristic “tramline” calcification, which outlines the convolutions of the parieto-occipital cortex. CT scanning and MRI show the abnormalities of the involved cortex at an earlier age.

This condition is generally referred to as the Sturge-Weber syndrome, since it was W. Allen Sturge, in 1879, who originally described a child with sensorimotor seizures contralateral to a facial “port-wine mark,” and Parkes Weber (1922, 1929), who gave the first radiographic demonstration of the atrophy and calcification of the cerebral hemisphere homolateral to the skin lesion. This eponym overlooks the important intervening contributions of Kalischer (1897, 1901), who first described the meningeal angioma in conjunction with the facial one; of Volland (1913), who demonstrated the intracortical calcific deposits; and of Dimitri (1923), who described the characteristic double-contoured radiographic shadows. Krabbe (1932, 1934) showed conclusively that the calcification lay not in the blood vessels (as Dimitri and many others had concluded) but in the second and third layers of the cortex (see [Wohlwill and Yakovlev](#) for historical review and bibliography).

It must not be thought that all cranial hemangiomas affect the cerebrum; facial nevi, especially the flat midline ones and the elevated strawberry nevi, are of no neurologic significance. And a cerebral meningeal angiomatosis may be present without skin lesions. The involvement of the upper eyelid is of greatest importance; nearly all such cases are associated with cerebral lesions ([Barlow](#)). There seems to be a close correlation between the persistence or maldevelopment of the embryonic vascular plexus of the eyelid and forehead and that of the occipitoparietal parts of the brain. When the nevus lies entirely below the upper eyelid or high on the scalp, a cerebral lesion is usually absent, although in a few instances such an angioma has been associated with a vascular malformation of the meninges overlying the brainstem and cerebellum. In angiograms, the abnormal meningeal vessels, which are largely veins, are not well seen; thus they can be distinguished from arteriovenous malformations. Meningeal nevi are rarely the source of subarachnoid or cerebral hemorrhage, and they do not enlarge to form a “mass lesion.” The cortical lesion is destructive in type; lost neurons are replaced by glial tissue that calcifies. Possibly diversion of blood to the meninges during seizures causes the progressive ischemia of the cerebral cortex. Barlow believes the seizures to be responsible for the progressive neurologic deficits and that a special effort should be made to prevent them by carefully regulated medical therapy. Occasionally surgical excision of intractable discharging foci may be necessary, but often this may not be feasible in view of the magnitude of the cerebral lesion. Radiotherapy is unsuccessful in reducing the skin blemish; sensitive individuals usually try to hide it with cosmetics.

Although the encephalotrigeminal syndrome is of congenital origin, its cause and pathogenesis are unknown. Familial coincidence has been observed but is

exceptional. No chromosomal abnormality has been demonstrated.

Dermatomal Hemangiomas with Spinal Vascular Malformations A hemangioma of the spinal cord may rarely be accompanied by a vascular nevus in the corresponding dermatome, as first pointed out by [Cobb](#). Such nevi are most frequent on the arm and trunk. When the cutaneous lesion involves an arm or leg, there may be enlargement of the entire limb or fingers in combination with underdevelopment of certain other parts (Klippel-Trenaunay-Weber syndrome). Some of these angiomatous syndromes, as well as those described by [Wyburn-Mason](#), combine a spinal or retinodiencephalic arteriovenous malformation (AVM) with a nevus of the trunk or face, respectively. Such cases provide a link to the common AVMs described in [Chap. 34](#).

The Epidermal Nevus Syndrome This is a closely related congenital neurocutaneous disorder in which a specific skin lesion (epidermal nevus or linear sebaceous nevus) is associated with a variety of hemicranial and neurologic abnormalities. The skull and brain abnormalities are ipsilateral to the nevus. One-sided thickening of the bones of the skull is characteristic. Mental retardation, seizures, and hemiparesis are the usual neurologic manifestations and have their basis in a wide variety of cerebral lesions—unilateral cerebral atrophy, porencephalic cyst, leptomenigeal hemangioma, arteriovenous malformation, and atresia of cerebral arteries and veins. The somatic and neurologic abnormalities have been comprehensively reviewed by [Solomon and Esterley](#) and by [Baker](#) and associates.

Familial Telangiectasia (Osler-Rendu-Weber Disease) This, a vascular anomaly transmitted as an autosomal dominant trait, affects the skin, mucous membranes, gastrointestinal and genitourinary tracts, and occasionally the nervous system. The basic lesion is probably a defect in the vessel wall, and bleeding is thought to be due to the mechanical fragility of the vessel. The lesions range from the size of a pinhead to 3 mm or more; they are bright red or violaceous and blanch under pressure. Located sparsely in the skin of any part of the body, they first appear during childhood, enlarge during adolescence, and may assume spidery forms, resembling the cutaneous telangiectases of cirrhosis in late adult life. The significance of the lesions lies in their hemorrhagic tendency. During adult years they may give rise to severe and repeated epistaxis or gastric, intestinal, or urinary tract bleeding and result in an iron-deficiency anemia. Pulmonary fistulas constitute another important feature of the generalized vascular dysplasia; patients with such lesions are particularly subject to brain abscesses and less so to bland embolic strokes.

The angiomas of this disease may form in either the spinal cord or brain, where they can produce apoplectic syndromes; or as in one of our patients, an intermittently progressive focal thalamic syndrome resulting from enlargement of the vascular lesions (or possibly from a succession of small hemorrhages). An unexplained gastrointestinal, genitourinary, intracranial, or intraspinal hemorrhage warrants a search for small cutaneous lesions, which are easily overlooked. Cautery eradicates a bleeding lesion, but satellite lesions tend to form.

Restricted Developmental Abnormalities of the Nervous System

In the course of clinical practice, one encounters a remarkable number of restricted disorders of the nervous system, many of which are transmitted from generation to generation as a mendelian dominant trait. Only a few of the more striking examples are described here. The reader may turn to books on genetics or teratology for an account of such oddities as hereditary unilateral ptosis, hereditary Horner syndrome, pupillary inequalities, jaw winking, absence of a particular muscle, etc.

Bifacial and Abducens Palsies (Möbius Syndrome) The syndrome of congenital facial diplegia with convergent strabismus is generally referred to as *Möbius syndrome*, although it had been described earlier by von Graefe. Its presence at birth is disclosed by the lack of facial movements and full eye closure. The most complete review of the subject in the English literature is that of Henderson. In his analysis of 61 cases of the congenital facial diplegia syndrome, there were 45 instances of abducens palsy, 15 of complete external ophthalmoplegia, 18 of lingual palsy, 17 of clubfeet, 13 of brachial disorders, 6 of mental defect, and 8 of an absent pectoral muscle. Thus the overlap with other neuromuscular and CNS abnormalities is evident. Early in life the mouth hangs open, the lower lip is everted, and there is difficulty in sucking. Usually this syndrome can be distinguished from the facial palsy of forceps or birth injury by its bilaterality and the other associated weaknesses. Occasionally more than one family member is affected (usually autosomal dominant inheritance). The cause of this peculiar condition is not known. The few adequate pathologic studies have shown a lack of nerve cells in the motor nuclei of the brainstem, changes that also characterize the Fazio-Londe syndrome (page 1162). Rarely, there may be an aplasia of facial muscles. The Möbius syndrome is also referred to on page 1531 in relation to restricted palsies of myopathic and nuclear origin.

Partial paralysis of facial muscles that dates from birth and cannot be attributed to obstetric trauma is not infrequent. In a common type, the lower lip on the involved side remains immobile when the child smiles or cries; the lip on the unaffected side is drawn downward and outward, resulting in a prominent asymmetry of the lower face. Often it is not appreciated that the side that droops during crying is the normal side ([Hoefnagel and Penry](#)).

Congenital Lack of Lateral Gaze (Oculomotor Apraxia of Cogan; See page 278) Children with this congenital defect are unable to turn their eyes to either side volitionally or on command. Attempting to look to the right, the child turns the head to the right (there is no associated apraxia of head turning, as in the acquired condition), but the eyes lag and turn to the left. As a result, the patient has to overshoot the mark with the head in order to attain ocular fixation. Once the eyes fixate, the head returns to the primary position. To compensate for the deficiency of eye movements, the patient develops jerky thrusting movements of the head, which characterize all attempts at voluntary gaze. Caloric stimulation of the labyrinth causes tonic movement of the eyes but not nystagmus, as in the normal person. Also, optokinetic nystagmus cannot be induced. Vertical movements are normal, however. A similar ocular condition may occur in conjunction with ataxia-telangiectasia and Gaucher disease. These children are slow to walk, and Ford observed one such child whose sibling had an absence of the vermis of the cerebellum. Aside from this observation, the anatomic basis of this condition has not been studied.

CONGENITAL ABNORMALITIES OF MOTOR FUNCTION

In this group of congenital disorders, a major disturbance of motor function, usually nonprogressive, has been present since infancy or early childhood. The popular terms for these conditions have been *infantile cerebral paralysis* ([Freud](#)) and *cerebral palsy*. The latter name is not appropriate, nor is it useful from the physician's viewpoint, collocating, as it does, diseases of widely differing etiologic and anatomic types, wherein the hereditary and acquired and the intrauterine, natal, and postnatal diseases lose their identity. Unfortunately the name has been adopted as a slogan for fund-raising societies and for all manner of rehabilitation clinics throughout the United States, so that it will not soon disappear from medical terminology. The term often abbreviated ("CP") is still being used indiscriminately by laymen and many physicians to designate every conceivable cognitive and motor disorder of corticospinal, extrapyramidal, cerebellar, and even neuromuscular type in infants and children.

Etiology of the Congenital Cerebral Motor Disorders

Motor abnormalities that have had their onset early in life are numerous and diverse in their clinical manifestations. Marked prematurity is a determining factor in a large proportion of cases. Each year, about 50,000 infants weighing less than 1500 g are born in the United States. Approximately 85 percent survive, and of these, 5 to 15 percent have a motor disorder of cerebral origin and 25 to 30 percent are mentally impaired at school age ([Volpe](#); see also [Hack et al](#)). To ascertain the etiologic and pathogenic factor(s), it is helpful to categorize a given case according to the extent and nature of the motor abnormality. A careful history of possible prenatal, perinatal, or postnatal insults to the developing nervous system must always be sought; certain correlations of these factors with the resulting pattern of neurologic deficit are outlined below. Most patients with these motor abnormalities of infancy and childhood reach adult years. Many of them have some degree of mental retardation and epilepsy in addition to the motor abnormalities, and there is an unavoidable overlapping in any consideration of the mechanisms of these three clinical states.

The following discussion of these problems is centered on three major etiologic syndromes—matrix hemorrhages in the immature infant, hypoxic-ischemic encephalopathy (Little disease), and certain developmental motor abnormalities.

Matrix (Subependymal) Hemorrhage in Premature Infants In low-weight immature infants (20 to 35 weeks gestational age), there often occurs, within a few days after birth, a catastrophic decline in cerebral function, usually preceded by respiratory distress (hyaline-membrane disease), with cyanosis and apneic spells. Also seen are failure of brainstem automatisms (sucking and swallowing), bulging of the fontanel, and appearance of sanguineous CSF. Once the infant becomes completely unresponsive, death usually ensues within a few days. Autopsy discloses a small lake of blood in each cerebral hemisphere (often asymmetrical), occupying the highly cellular (subependymal) germinal matrix, near the caudate nucleus at the level of the foramen of Monro. This region is supplied by the lenticulostriate, choroidal, and Heubner's recurrent arteries and is drained by deep veins, which enter the vein of Galen. In about 25 percent of cases, the blood remains loculated in the matrix zone, while in the others it ruptures into the lateral ventricle or adjacent brain tissue. In a series of 914 consecutive autopsies in newborns, subependymal hemorrhage was found in 284 (31 percent); practically all of these neonates were of low birth weight ([Banker and Bruce-Gregorios](#)).

Lesser degrees of this complex of cerebral lesions are now being identified by ultrasonography ([Fig. 38-12](#)) and CT scans, and it is apparent that many infants with

lesions of lesser magnitude survive. Some rapidly develop an obstructive hydrocephalus and require a ventricular shunt. In others, the hydrocephalus stabilizes and there is clinical improvement. Several series of surviving cases have now been followed for many years. Those in whom the hemorrhage was relatively more extensive are often left with motor and intellectual handicaps. In the Swedish series of Hagberg and Hagberg, 55 percent of the patients with spastic diplegia had preterm births and the neuropathologic basis was believed to be matrix hemorrhage, leukomalacia (see further on), or both. Congenital hemiplegia or quadriplegia are observed at lower frequency. In another series of 20 cases of posthemorrhagic hydrocephalus ([Chaplin et al](#)), 40 percent had significant motor deficits and over 60 percent had IQ scores of less than 85. In a personal experience with 12 less severe cases (mean birth weight 1.8 kg and gestational age of 32.3 weeks), only one had a residual spastic diplegia and 9 of the 12 had IQs in the low-normal or normal range. The average age of the children at the time of the last evaluation was 8.5 years.

Figure 38-12 *Ultrasound demonstration of subependymal matrix hemorrhage in a premature infant (arrow).*

The cause of this unique form of matrix hemorrhage is unsettled. In all probability it is related to greatly increased pressure in the thin-walled veins of the germinal matrix, coupled with a lack of adequate supporting tissue in these zones. The increased blood pressure or venous pressure is, in turn, manifestly related to the pulmonary disorders that occur in immature infants. These infants are also prone to the development of characteristic lesions of the cerebral white matter ([periventricular leukomalacia](#), see below), and the residual neurologic deficits are the result of these lesions, added to the deficits due to the subependymal hemorrhage (mainly hydrocephalus). Acetazolamide and furosemide, which reduce the formation of spinal fluid and have been widely used in the treatment of posthemorrhagic ventricular dilatation, have been shown, in a large-scale controlled study, to be of little value in reducing the need for shunt placement (see [International PHVD Drug Trial Group](#) in the References).

Periventricular Leukomalacia These are zones of necrosis of white matter in the deep watershed territories of cortical and central arteries. They lie lateral and posterolateral to the lateral ventricles, in a position to involve the occipital radiations and the sensorimotor fibers in the corona radiata ([Banker and Larroche](#); [Shuman and Selednik](#)). These white-matter lesions occur in about one-third of cases of subependymal hemorrhage, but they may develop independently in both premature and full-term infants who have suffered hypotension and apnea. In a study of 753 preterm infants, those born at 28 weeks gestation were at highest risk of this complication; the combination of intrauterine infection and premature rupture of membranes carried a 22 percent risk ([Zupan et al](#)). Survivors often manifest cerebral diplegia and mental impairment. The motor disorder is usually more severe than the cognitive and language impairment.

Control of respiratory distress may reduce the incidence of matrix hemorrhages and periventricular leukomalacia. Claims have been made that the administration of indomethacin ethamsylate, a drug that reduces capillary bleeding, and the intramuscular injection of vitamin E for the first 3 days after birth and possibly the use of betamethasone reduce the incidence of periventricular hemorrhage ([Benson et al](#); [Sinha et al](#); see also [Volpe](#) for discussion of control of cerebral hemodynamics and effects of drugs in the neonatal period.)

Hypoxic-Ischemic Damage Little's conception of the hypoxic-ischemic form of "birth injury," enunciated in 1862, has been subjected to scrutiny over the years. While it is evident that many newborns suffer some degree of perinatal asphyxia, relatively few of them seem to manifest brain damage. Moreover, many infants with a variety of cerebral motor syndromes appear to have passed the parturitional (perinatal) period without mishap, indicating the greater importance of other prenatal and postnatal causative factors. Nonetheless, severe neonatal asphyxia of term or preterm babies is an important cause of spastic-dystonic-ataxic syndromes, often accompanied by seizures and mental subnormality.

One has the impression that the CNS tolerates hypoxia and reduced blood flow in the postnatal period better than at any other time in life. Indeed, animal experimentation supports this view. Not until the arterial O₂ tension is reduced to 10 to 15 percent of normal does brain damage occur, and even then the impaired function of other organs contributes to the damage; nearly always there are irregularities of the heart and hypotension from myocardial damage as well as hepatic and renal failure. Thus it is more correct to think of the encephalopathy in terms of both hypoxia and ischemia, which usually occur in utero and are expressed postnatally by recognizable clinical syndromes.

As regards the cerebral syndromes that do follow an obviously difficult birth (reflected by low 5-min Apgar scores and the need of resuscitative measures), Fenichel finds it helpful to divide them into three groups, according to their severity: (1) In newborns with mild hypoxic-ischemic encephalopathy, the symptoms are maximal in the first 24 h and take the form of hyperalertness and tremulousness of the limbs and jaw (the "jittery baby") and a low threshold of the Moro reaction. The tone of the limbs is normal except for a mild increase in head lag during traction. The reflexes are brisk and there may be ankle clonus. The anterior fontanel is soft. The EEG is normal. Recovery is complete and the risk of handicap is extremely low. (2) Newborns with moderate hypoxic-ischemic encephalopathy are lethargic, obtunded, and hypotonic, with normal movements. After 48 to 72 h, the neonate may improve (having passed through a jittery hyperactive phase) or worsen, becoming less responsive in association with convulsions, cerebral edema, hyponatremia, and hyperammonemia from liver damage. The EEG is abnormal; Fenichel associates epileptiform activity and voltage suppression with an unfavorable outcome. Abnormal visual and auditory evoked potentials are other poor prognostic signs. (3) In neonates with severe hypoxic-ischemic encephalopathy, stupor or coma are present from birth; respirations are irregular, requiring mechanical ventilation. There are usually convulsions within the first 12 h. The limbs are hypotonic and motionless even in attempts to elicit the Moro response. Sucking and swallowing are depressed, but pupillary reactions and eye movements may at first be retained, only to be lost as the coma deepens.

It is in the second and third categories, i.e., the states of moderate to severe encephalopathy, where correction of the respiratory insufficiency and the metabolic abnormalities permits survival, that a number of motor abnormalities (corticospinal, extrapyramidal, and cerebellar) and mental retardation eventually emerge. Included in the category of severe hypoxic-ischemic encephalopathy are also newborns with a variety of developmental anomalies of the brain and other organs. In addition, they may have been exposed to certain prenatal risk factors (toxemia of pregnancy, antepartum uterine hemorrhage), or their growth may have been abnormal (small-for-date babies). Some are born at term; others are premature, and the birth process may or may not have been abnormal. One must then consider the possibility, originally pointed out by [Sigmund Freud](#), that the abnormality of the birth process, instead of being causal, was actually the consequence of prenatal pathology. The latter might include preterm intrauterine hypoxia-ischemia.

Other evidence of multifactorial etiology in the "causation" of cerebral palsy has been provided by [Nelson and Ellenberg](#), who found that maternal mental retardation, birth weight below 2000 g, and fetal malformation were among the leading predictors. Breech presentation was another factor, and one-third of these cases also had a noncerebral malformation. Twenty-one percent of the 189 children in their series had also suffered some degree of asphyxia. Additional determinants were maternal seizures, a motor deficit in an older sibling, two or more prior fetal deaths, hyperthyroidism in the mother, pre-eclampsia, and eclampsia. In children with cerebral diplegia born at term, likely contributory factors that were operative in nearly half of them included toxemia of pregnancy, low birth weight for age (indicating undernutrition), placental infarction, and intrauterine asphyxia.

The factors enumerated above are involved to different degrees in the outcome of pregnancies but are informative because they bring to light the significant proportion of cases of cerebral birth injury in which hypoxia-ischemia, matrix hemorrhages, and leukomalacia were not operative. In this last group, we would also include the symmetrical porencephalies and hydranencephalies (see also page 1053). The porencephalic cerebral defect, if unilateral, is usually in the frontal lobe and is a cause of congenital hemiplegia. If the defect is bilateral, there is bilateral hemiplegia as well as severe impairment of mental development. In hydranencephaly, the greater part of both cerebral hemispheres is replaced by a membrane. Only the inferior temporal and occipital lobes remain, along with the thalamus and basal ganglia. The cranium may be full-sized or enlarged. Such children survive for only a short time (weeks, months, or a few years), functioning

essentially as brainstem preparations. CT scanning and MRI facilitate the recognition of both of these disorders.

Clinical Syndromes of Congenital Motor Disorders With reference to the types of motor disorder evolving from the four major categories of cerebral disease—matrix hemorrhage, periventricular leukomalacia, hypoxic-ischemic encephalopathy, kernicterus (discussed further on)—the most frequent is spastic diplegia; i.e., motor disturbances are severe in the lower limbs and mild in the upper. In addition to diplegia, hypoxic-ischemic injury occurring in the term or preterm infant may take the form of a hemiplegia, double hemiplegia (quadriplegia), or a mixed pyramidal-extrapyramidal or spastic-ataxic syndrome.

A second form of motor disorder is characterized by the development of severe spastic quadriplegia and mental retardation. The major insult is intrapartum asphyxia and attendant fetal distress. Usually such infants will have required resuscitation and will have had low 5-min Apgar scores, which in this circumstance have important predictive value. The pathologic lesions of the brain in this second group consist of hypoxic-ischemic infarction in distal fields of arterial flow, primarily in the cortex and white matter of parietal and posterior frontal lobes, leaving a ulegyric sclerotic cortex.

A third group, also discussed below, is characterized mainly by extrapyramidal abnormalities, combining athetosis, dystonia, and ataxia in various proportions. In summarizing several large series of congenital and neonatal motor disorders, spastic diplegia occurred in 10 to 33 percent of cases, spastic quadriplegia 19 to 43 percent, extrapyramidal forms in 10 to 22 percent, and mixed forms in 9 to 20 percent.

Spastic Diplegia (Cerebral Spastic Diplegia; Little Disease) The pattern of paralysis is more variable than the term *spastic diplegia* implies; actually, several subtypes may be distinguished: the paraplegic, diplegic, quadriplegic, pseudobulbar, and generalized. Pure paraplegic and pseudobulbar types are relatively rare. Usually all four extremities are affected, but the legs much more than the arms, which is the real meaning of *diplegia*. Hypotonia—with retained tendon reflexes and hypoactivity—is usually present initially. Only after the first few months will evident weakness and spasticity appear, first in the adductors of the legs. The plantar reflexes, which are often ambiguous in the normal infant, here are clearly extensor, a finding that is pathologic at any later age. Also, stiff, awkward movements of the legs, which are maintained in an extended, adducted posture when the infant is lifted by the axillae, often do not attract attention until several weeks or months have passed. Seizures occur in approximately one-third of the cases, and it is not uncommon to observe a delay in all developmental sequences, especially those that depend on the motor system. Once walking is attempted, usually at a much later date than normal, the characteristic stance and gait become manifest. The slightly flexed legs are advanced stiffly in short steps, each describing part of an arc of a circle; adduction of the thighs is often so strong that the legs may actually cross (scissors gait); the feet are flexed and turned in with the heels not touching the ground. In the adolescent and adult, the legs tend to be short and small, but the muscles are not markedly atrophic, as in spinal muscular atrophy. Passive manipulation of the limbs reveals spasticity in the extensors and adductors and slight shortening of the calf muscles. The arms may be affected only slightly or not at all, but there may be awkwardness and stiffness of the fingers and, in a few, pronounced weakness and spasticity. In reaching for an object, the hand may overpronate. Speech may be well articulated or noticeably slurred, and in some instances the face is set in a spastic smile. The deep tendon reflexes are exaggerated, those in the legs more than the arms; the plantar reflexes are extensor in the majority of cases. Scoliosis is frequent and may secondarily give rise to spinal cord and root compression and impaired respiratory function. As a rule, there is no disturbance of sphincteric function, though delay in acquiring voluntary control is usual. Athetotic postures and movements of the face, tongue, and hands are present in some patients and may actually conceal the spastic weakness; ataxic and hypotonic forms also exist (see further on).

One subtype of spastic diplegia is associated with a relatively slight diminution in head size and intelligence. As indicated above, there is no unifying neuropathology; the condition occurs independently of matrix hemorrhages and periventricular leukomalacia as well as with them. The frequency of cerebral spastic diplegia, which is closely related to the degree of prematurity, has declined significantly since the introduction of neonatal intensive care facilities, and there is reason to believe that heredogenetic factors are of importance.

Infantile Hemiplegia, Paraplegia, and Quadriplegia Hemiplegia is a common condition of infancy and early childhood. The functional difference between the two sides may be noticed soon after birth, but more often it is not perceived by the mother until after the first 4 to 6 months of life. In a second group, the child is in excellent health for a year or longer before the abrupt onset of hemiplegia (see below). In hemiplegia that dates from earliest infancy—i.e., congenital hemiplegia—the parents first notice that movements of prehension and exploration are carried out with only one arm. A manifest hand preference at an early age should always raise the suspicion of a unilateral motor defect. The affection of the leg is usually recognized later, i.e., during the first attempts to stand and walk. Sitting and walking are usually delayed by a few months. In the older child, there is evident hyperactivity of tendon reflexes and usually a Babinski sign. The arm is held flexed, adducted, and pronated, and the foot assumes an equinovarus posture. Sensory and visual field defects are present in some patients. Mental defect may be associated with infantile hemiplegia but is less common and lesser in degree than with cerebral diplegia and much less common than with bilateral hemiplegia. There may also be speech delay, regardless of the side of the lesion; when this is present, one should look for mental retardation and expect to find a bilaterality of motor abnormality. Convulsions occur in 35 to 50 percent of children with congenital hemiplegia, and these may persist throughout life. They may be generalized but are frequently unilateral and limited to the hemiplegic side. Often, after a series of seizures, the weakness on the affected side will be increased for several hours or longer (Todd's paralysis). Gastaut and associates have described a hemiconvulsive-hemiplegic syndrome in which the progressive paralysis and cerebral atrophy are attributed to the convulsions. As months and years pass, the osseous and muscular growth of the hemiplegic limbs is retarded, leading to an obvious hemiatrophy.

With respect to the causation of congenital hemiplegia, it is generally agreed that perinatal asphyxia is only one of the possibilities. In the series of 681 children with “cerebral palsy” collected by [Hagberg and Hagberg](#), there were 244 with hemiplegia. Of the latter, 189 were full-term babies and 55 preterm. Prenatal risk factors were identified in only 45 percent, and they were mostly in the infants born prematurely. In nearly half of the cases, there was no clue as to the time in the intrauterine period when the cerebral lesion occurred.

In the second group—*acquired infantile hemiplegia*—a normal infant or young child, usually between the ages of 3 to 18 months, develops a massive hemiplegia, with or without aphasia, within hours. The disorder often begins with seizures, and the hemiplegia may not be recognized until the seizures have subsided. In Banker's autopsy series, there was arterial or venous thrombosis in some cases, but in many no occlusions were found. Some of the latter cases, in which arteriography had been negative, may have been embolic, possibly of cardiac origin. If the stroke occurs at an early age, the recovery of speech may be complete, though reduced scholastic capacity remains. The degree of recovery of motor function varies. Often, as the deficit recedes, the arm becomes involved by athetotic, tremulous, or ataxic movements. There may be an interval of months or years between the hemiplegia and the athetosis.

Encephaloclastic (destructive) lesions underlie most of the cases of infantile hemiplegia and some cases of bilateral hemiplegia. The pathologic change is essentially that of ischemic necrosis. In many cases, the lesions must have been incurred in utero. (Precipitant delivery, fetal distress, and prepartum uterine hemorrhage may be indications of the process.) The lesions reflect not only the effects of anoxia but also those of circulatory insufficiency (ischemia), the result of hypotension or circulatory failure. The ischemia of circulatory failure tends to affect the tissues lying in arterial border zones, and there may also be venous stasis with congestion and hemorrhage (occurring particularly in the deep central structures such as the basal ganglia and periventricular matrix zones). If they are purely hypoxic, the lesions should be bilateral. Myers has reproduced such lesions in the neonatal monkey by reducing the maternal circulation over a period of several hours. As the lesions heal, the monkeys develop the same ulegyric sclerotic changes in the cortex and white matter of the cerebrum (lobar sclerosis) and the “marbling” (état marbré) that characterize the brains of patients with spastic diplegia and double athetosis (see below).

The quadriplegic state differs from bilateral hemiplegias in that the bulbar musculature is often involved in the latter and mental retardation is more severe. The condition is relatively rare and is usually due to a bilateral cerebral lesion. However, one should also be alert to the possibility of a high cervical cord lesion. In the infant, this is usually the result of a fracture-dislocation of the cervical spine incurred during a difficult breech delivery. Similarly, in paraplegia, with weakness or paralysis limited to the legs, the lesion may be either a cerebral or a spinal one. Sphincteric disturbances and a loss of somatic sensation below a certain level on the trunk always point to a spinal localization. Congenital cysts, tumors, and diastematomyelia are more frequently causes of paraplegia than of quadriplegia. Another recognized cause of infantile paraplegia is spinal cord infarction from thrombotic complications of umbilical artery catheterization.

Extrapyramidal Syndromes The spastic cerebral diplegias discussed above shade almost imperceptibly into the congenital extrapyramidal syndromes. Patients with these latter syndromes are found in every cerebral palsy clinic, and ultimately they reach adult neurology clinics as well. Corticospinal tract signs may be completely absent, and the student, familiar only with the syndrome of pure spastic diplegia, is always puzzled as to their classification. Some cases of extrapyramidal type are undoubtedly attributable to severe perinatal hypoxia and others to diseases such as erythroblastosis fetalis with kernicterus. In order to state the probable pathologic basis and future course of these illnesses, it is desirable to separate the extrapyramidal syndromes of prenatal-natal origin (which usually become manifest during the first year of life) from the acquired or hereditary postnatal syndromes, such as familial athetosis, Wilson disease, dystonia musculorum deformans, and the hereditary cerebellar ataxias, which become manifest later.

Double Athetosis This is probably the most frequent of the congenital extrapyramidal disorders. In our clinical material and in reported series of cases, two types stand out—one that is due to hyperbilirubinemia or Rh incompatibility ([kernicterus](#), see below) and the other due to hypoxic-ischemic encephalopathy. With control of neonatal hyperbilirubinemia (by use of anti-Rh immune globulin, exchange transfusions, and phototherapy), kernicterus has almost disappeared, whereas the other,

more severe hypoxic-ischemic form regularly continues to be seen. Rarely, a congenital, nonhemolytic icterus or a glucose-6-phosphate dehydrogenase deficiency produces the same syndrome.

Like the spastic states, double athetosis may not be recognized at birth but only after several months or a year have elapsed. In some cases the appearance of choreoathetosis is delayed for several years, and it may seem to progress during adolescence and even early adult life. It must then be differentiated from some of the inherited metabolic and degenerative extrapyramidal diseases. Chorea and athetosis dominate the clinical picture, but bewildering combinations of involuntary movements—including dystonia, ataxic tremor, myoclonus, and even hemiballismus—may be found in a single case. At times, we have been unable to classify the movement disorder because of its complexity. It should be noted that practically all instances of double athetosis are also associated with a defect in voluntary movement.

Choreoathetosis in infants and children varies greatly in severity. In some, the abnormal movements are so mild as to be misinterpreted as restlessness or “the fidgets”; in others, every attempted voluntary act provokes violent involuntary movements, leaving the patient nearly helpless. The clinical appearance of choreoathetosis and other involuntary movements is discussed in [Chap. 4](#).

An early hypotonia, followed by retardation of motor development, is the rule in these cases. Erect posture and walking may be delayed until the age of 3 to 5 years and may never be attained in some patients. Tonic neck reflexes or fragments thereof tend to persist well beyond their usual time of disappearance. The plantar reflexes are usually flexor, though they may be difficult to interpret because of the continuous flexion and extension of the toes. Sensory abnormalities are not elicited. Because of the motor and speech impairment, patients are often erroneously thought to be mentally defective. In some, this conclusion is doubtless correct, but in others intellectual function is adequate, and a few can be educated to a high level.

A variety of rehabilitative measures have been tried: physiotherapy, surgery, sensory integrative therapy, progressive patterned movement, and neuromuscular facilitation. We agree with Hur, who has critically reviewed this subject, that properly controlled studies provide no proof of the success of any of these measures. Surely, with growth and development, new postures and motor capacities are acquired. The less severely affected patients can even make successful occupational adjustments. The more severely affected ones rarely achieve a degree of motor control that permits them to live independently. One sees some of these unfortunate persons bobbing and twisting laboriously as they make their way in public places.

Imaging studies are seldom of diagnostic value. Mild cerebral atrophy and loss of volume of the basal ganglia are seen in some cases, and cavitory lesions are present in some of the severe anoxic encephalopathies. The EEG is rarely helpful unless there are seizures.

The most frequent pathologic finding in the brain has been a whitish, marble-like appearance of the putamen, thalamus, and border zones of the cerebral cortex. These whitish strands represent foci of nerve cell loss and gliosis with condensation of adjacent transversing myelinated fibers—so-called *status marmoratus* (*état marbré*). This lesion does not develop after infancy, i.e., after the myelination glia have completed their developmental cycle.

Kernicterus This is now a rare cause of extrapyramidal motor disorder in children and adults. Such cases raise the broader question of the neurologic sequelae of erythroblastosis fetalis secondary to Rh and ABO blood incompatibilities or to a deficiency of the hepatic enzyme glucuronosyltransferase. The symptoms of kernicterus appear in the jaundiced neonate on the second or third postnatal day. The infant becomes listless, sucks poorly, develops respiratory difficulties as well as opisthotonos (head retraction), and becomes stuporous as jaundice intensifies. The serum bilirubin is usually greater than 25 mg/dL. In acidotic and hypoxic infants (e.g., those with low birth weight and hyaline membrane disease), the kernicteric lesions develop with much lower levels of serum bilirubin.

The majority of infants with this disease die within the first week or two of life. Many of those who survive are mentally retarded, deaf, hypotonic, totally unable to sit, stand, or walk, and spend their lives in homes for the feeble-minded. There are exceptional patients, however, obviously less damaged, who are mentally normal or at most only slightly backward. These are the ones who develop a variety of persistent neurologic sequelae—choreoathetosis, dystonia, and rigidity of the limbs—a picture not too different from that of cerebral spastic diplegia with involuntary movements. Kernicterus should always be suspected if an extrapyramidal syndrome is accompanied by bilateral deafness and palsy of upward gaze. Later there may be a greenish pigmentation of the dental enamel.

Neonates who die in the acute stage of kernicterus show a unique yellow staining (icterus) of nuclear masses (Kern nuclei) in the basal ganglia, brainstem, and cerebellum. In surviving patients the pathologic changes consist of a symmetrically distributed nerve cell loss and gliosis in the subthalamic nucleus of Luys, the globus pallidus, the thalamus, and the oculomotor and cochlear nuclei; these lesions are the result of the hyperbilirubinemia. The immature cerebral cortex is usually spared. In the newborn, unconjugated bilirubin can pass through the poorly developed blood-brain barrier into these nuclei, where it is directly toxic. Acidosis and hypoxia exacerbate the effect. Also in the newborn, the development of hyperbilirubinemia is enhanced by a transient deficiency of the enzyme glucuronosyltransferase, essential for the conjugation of bilirubin. *Hereditary hyperbilirubinemia*, due to lack of this enzyme (*Crigler-Najjar syndrome*), may have the same effect on the nervous system at a later period of infancy or childhood as hyperbilirubinemia due to Rh incompatibility.

Immunization, phototherapy, and exchange transfusions with female blood, designed to prevent high levels of unconjugated serum bilirubin, have been shown to protect the nervous system. If the blood bilirubin level can be held to less than 20 mg/dL (10 mg/dL in prematures), the nervous system may escape damage. The effective use of these measures has practically eradicated this dreaded disease.

Both kernicterus and ischemic *état marbré* must be differentiated clinically from hereditary choreoathetosis, the Lesch-Nyhan syndrome, and—later in life—from ataxia-telangiectasia and Friedreich ataxia.

Congenital and Neonatal Ataxias In these patients, difficulty in standing and walking cannot be attributed to spasticity or paralysis. Again, hypotonia and poverty of movement are the initial motor abnormalities; the cerebellar deficit becomes manifest at a later time, when the patient begins to sit, stand, and walk. There may or may not be a delay in reaching “motor milestones.” Attempts to attain sitting balance will first reveal an unsteadiness that is not soon overcome, even with practice. Reaching for a proffered toy is accomplished by jerky, incoordinated movements. The first steps are unsteady, as would be expected, with many tumbles, but the gait remains clumsy. Instability of the trunk may be accompanied by similar, more or less rhythmic movements of the head, so-called titubation. Despite the severity of the ataxia, the muscles are of normal size, and voluntary movements, though weak in some patients, are possible in all the limbs. The tendon reflexes are present, and the plantar reflexes are either flexor or extensor. In some cases, the ataxia is associated with spasticity rather than hypotonia (spastic-ataxic diplegia). Relative improvement may occur in later years. In the older child, a cerebellar gait, ataxia of limb movements, nystagmus, and uneven articulation of words are readily distinguished from myoclonus, chorea, athetosis, dystonia, and tremor.

In only a few cases have the pathologic changes been studied. Aplasia or hypoplasia of the cerebellum has been observed, but sclerotic lesions of the cerebellum are more common. The CT scan or MRI verifies the cerebellar atrophy. A cerebral and cerebellar lesion may coexist in patients with congenital ataxia, which is the reason for the term *cerebrocerebellar diplegia*.

Several risk factors have been identified in the congenital ataxias. A genetic factor is operative in some cases ([Hagberg and Hagberg](#)). Radiation of the maternal abdomen during the first trimester of pregnancy is said to have resulted in cerebellar hypoplasia. Mercury poisoning in utero is another cause of congenital ataxia. Most importantly, cerebellar ataxia may be the most prominent or sole effect of neonatal ischemia-hypoxia.

Pontocerebellar Hypoplasias Aside from the congenital ataxia described above, there are several rare familial forms in which a failure of cerebellar development is associated with mental retardation. Joubert reported a family in which there was dysgenesis of the vermis of the cerebellum, mental retardation, episodic hyperpnea, irregular, jerky eye movements, and unsteady gait. The syndrome appeared in 4 of 6 siblings. In other reports, choroidal-retinal colobomas, polydactyly, cryptorchidism, and prognathism have been mentioned. Detailed examination of the cerebra of such cases is needed. In the *Gillespie syndrome*, a combination of aniridia, cerebellar ataxia, and mental retardation are the denominating features. In the *Paine syndrome*, a familial disorder with developmental delay and mental retardation, there is microcephaly, spasticity, optic hypoplasia, and myoclonic ataxia, the last presumably related to the cerebellar hypoplasia. These dysgeneses and the disequilibrium syndrome reported from Sweden are brought together by the cerebellar ataxia; in the past, they fell into the group of ataxic cerebral palsies. Imaging studies demonstrate the cerebellocerebral abnormality. Genetic factors are operative in some, but matters pertaining to etiology remain obscure (see [Harding](#) for details). A pure congenital cerebellar hypoplasia has been mapped to a gene locus on chromosome Xq ([Illarioshkin et al](#)). The ataxia was inherited as an X-linked recessive trait and was nonprogressive beyond early childhood.

Differential Diagnosis of the Congenital Ataxias The congenital ataxias must be distinguished from the progressive hereditary ataxias. The latter are likely to begin at a later age than the congenital ones. Some hereditary ataxias are intermittent or episodic. They are discussed in page 1010. Several forms of childhood ataxia are

neither congenital nor hereditary; they have an acute onset and may persist during childhood, adolescence, and adult life.

Also to be distinguished from the ataxias of congenital and neonatal origin is an *acute cerebellar ataxia of childhood*, which can usually be traced to a viral infection or a postinfectious encephalitis, particularly after chickenpox. The *opsoclonus-myoclonus (“dancing eyes”) syndrome* of Kinsbourne is another postinfectious disease peculiar to childhood (see pages 977 and 1097). The cerebellar ataxia in this disease may be overshadowed by polymyoclonus, which marks every attempted movement. With improvement, under the influence of corticosteroids, a cerebellar disorder of speech and movement becomes evident. A majority of the cases in which the disease becomes chronic (16 of the 26 cases followed by [Marshall et al](#)) were found later to be mentally backward. The cause of the disease has never been established. An occult neuroblastoma or other tumor is uncovered occasionally.

Yet another form of cerebellar ataxia, which is inherited as an autosomal dominant trait, occurs in discrete attacks. It usually begins in childhood and persists through adult life. In two of our patients, it began in mid-adult life; one form is improved by the administration of acetazolamide (see page 1022).

In the differential diagnosis of these acute forms of cerebellar ataxia, one must not overlook intoxication with phenytoin, barbiturates, or similar drugs.

The Flaccid Paralyzes The cerebral form, first described by Foerster and called *cerebral atonic diplegia*, has already been mentioned. It can usually be distinguished from the paralysis of spinal and peripheral nerve origin and congenital muscular dystrophy by the retention of postural reflexes (flexion of the legs at the knees and hips when the infant is lifted by the axillae), preservation of tendon reflexes, and coincident failure of mental development.

The syndrome of *infantile spinal muscular atrophy (Werdnig-Hoffmann disease)* is the leading example of flaccid paralysis of lower motor neuron type. Perceptive mothers may be aware of a paucity of fetal movements in utero, and in most cases the motor defect becomes evident soon after birth or the infant is born with arthrogryptic deformities. Several other types of familial progressive muscular atrophy have been described in which the onset is in early or late childhood, adolescence, or early adult life. Weakness, atrophy, and reflex loss without sensory change are the main features and are discussed in detail in [Chap. 39](#). A few patients suspected of having infantile or childhood muscular atrophy prove, with the passage of time, to be merely inactive “slack” children, whose motor development has proceeded at a slower rate than normal. Others may remain weak throughout life, with thin musculature. These and several other congenital myopathies—*central core, rod-body, nemaline, mitochondrial, myotubular, and fiber type disproportion and predominance*—are described in [Chap. 52](#). Unlike Werdnig-Hoffmann disease, the effects of many of them tend to ameliorate as the natural growth of muscle proceeds. Rarely, polymyositis and acute idiopathic polyneuritis manifest themselves as a syndrome of congenital hypotonia.

Infantile muscular dystrophy and lipid and glycogen storage diseases may also produce a clinical picture of progressive atrophy and weakness of muscles. The diagnosis of *glycogen storage disease* (usually the Pompe form) should be suspected when progressive muscular atrophy is associated with enlargement of the tongue, heart, liver, or spleen. The motor disturbance in this condition may be related in some way to the abnormal deposits of glycogen in skeletal muscles, though it is more likely due to degeneration of anterior horn cells that are also distended with glycogen and other substances. Certain forms of *muscular dystrophy* (myotonic dystrophy and several types of congenital dystrophy) may also be evident at birth or soon thereafter. The latter may have led to arthrogryposis and club foot (see page 1530). All of these disorders are described in detail in the chapters on muscle diseases.

Brachial plexus palsies, well-known complications of dystocia, usually result from forcible extraction of the fetus by traction on the shoulder in a breech presentation or from traction and tipping of the head in a shoulder presentation. The effects of such injuries are sometimes lifelong. Their neonatal onset is betrayed later by the small size and inadequate osseous development of the affected limb. Either the upper brachial plexus (fifth and sixth cervical roots) or the lower brachial plexus (seventh and eighth cervical and first thoracic roots) suffer the brunt of the injury. Upper plexus injuries (Erb) are about 20 times more frequent than lower ones (Klumpke). Sometimes the entire plexus is involved (page 1427).

Facial paralysis, due to forceps injury to the facial nerve immediately distal to its exit from the stylomastoid foramen, is another common (usually unilateral) peripheral nerve affection in the newborn. Failure of one eye to close and difficulty in sucking make this condition easy to recognize. It must be distinguished from the congenital facial diplegia that is often associated with abducens palsy, i.e., the Möbius syndrome discussed earlier in the chapter. In most cases of facial paralysis due to physical injury, function is recovered after a few weeks; in some, the paralysis is permanent and may account for lifelong facial asymmetry.

In summary, it can be said that all these forms of disabling motor abnormalities rank high as important issues in neuropediatrics. Steps have been taken in most hospitals to identify and eliminate risk factors in attempts at prevention. Indeed, better prenatal care, reduction in premature births, and control of respiratory problems in critical care wards have reduced their incidence and prevalence. Physical and mental therapeutic measures appear to be helpful, but many of the methods have been difficult to evaluate in a nervous system undergoing maturation and change. The neurologist can contribute most by segregating groups of cases of identical pattern and etiology and in differentiating the congenital groups of delayed expressivity from the treatable acquired diseases of this age period. Woefully lacking are critical neuropathologic studies.

INTRAUTERINE AND NEONATAL INFECTIONS

Throughout the intrauterine period the embryo and fetus are subject to particular infections. Since the infective agent must reach the fetus through the placenta, it is evident that the permeability of the latter at different stages of gestation and the immune status of the maternal organism are determinative. We are including a discussion of these intrauterine infections here because some of them may lead to malformations of the brain and, later in life, must be distinguished from developmental abnormalities.

Until the third to fourth month of gestation, the large microbial organisms—such as bacteria, spirochetes, protozoa, and fungi—cannot invade the embryo, even though the mother harbors the infection. Viruses may do so, however—specifically rubella, cytomegalovirus (CMV), human immunodeficiency virus (HIV), and possibly others. The rubella virus enters embryonal tissues during the first trimester, *Treponema pallidum* in the fourth to fifth postconceptional month, and *Toxoplasma* after that period. Bacterial meningitis (except for that due to *Listeria monocytogenes*, described below) is essentially a paranatal infection contracted during or immediately after parturition. Neonatal herpes simplex encephalitis, due to the type 2 (genital) virus, is also usually acquired by passage through an infected birth canal. Some cases of HIV infection may be acquired during delivery, but most are due to transplacental transmission.

The main neonatal infections—toxoplasmosis, rubella, cytomegalovirus and herpes—are commonly designated by the acronym TORCH. With the persistence of *Listeria*, the rise of AIDS infections, and a marked reduction in rubella infections, the mnemonic LATCH, which includes *Listeria* and AIDS, might be more appropriate. Infants with all these infections share certain common features, such as low birth weight, prematurity, congenital heart disease, purpura, jaundice, anemia, microcephaly or hydrocephaly, cerebral calcifications, choreoretinitis, cataracts, microphthalmia, and pneumonitis; as a corollary, if any combination of these features is manifest, one should suspect one of these infectious agents and take measures to identify it. However, in none of the types of infections are all these clinical manifestations likely to be present, and in the cases of rubella and cytomegalovirus, only a small percentage of infected infants will show major systemic signs or symptoms.. Nevertheless, on clinical grounds alone, certain of these infections can be identified and others excluded. For example, cerebral calcifications are present mainly in toxoplasmosis and CMV encephalopathy, being rare in rubella and absent in HSV encephalitis; the calcifications are widely disseminated in toxoplasmosis and have a periventricular distribution in CMV infection. Cardiac lesions are present only with rubella, and deafness occurs only with CMV and rubella. Thus, there are clinical signposts to guide the clinician in selecting the appropriate diagnostic tests. Most importantly, in considering neonatal infections, one must also search for other, non-LATCH infections (see [Chap. 32](#) and [Chap. 33](#)).

Added difficulty in the diagnosis of embryonal and fetal infections arises when the mother has been entirely asymptomatic. Isolation of the organism from fetal and neonatal tissues is possible, but usually they are inaccessible, and it may be impossible to demonstrate antibodies or other immune responses because of the early stage of the infection or limitations of the infant's immune response.

Rubella

Gregg, in 1941, first reported the association of maternal rubella and congenital cataracts in the neonate. His observations were quickly verified, and soon it became widely known that cataracts, deafness, congenital heart disease, and mental retardation constituted a kind of tetrad diagnostic of this disease. That a virus could affect so many tissues, causing in essence a noninflammatory developmental disorder of multiple organs, was a novel concept, and it raised the interesting prospect that other viruses might have similar effects. Surprisingly, however, only CMV and possibly herpes simplex viruses (HSV) have been incriminated in embryonal neuropathology. A large number of other viruses (e.g., influenza, Epstein-Barr, hepatitis) have been implicated in human teratogenesis, but in none is the relationship

beyond doubt.

It is now well established that most instances of congenital rubella infection occur in the first 10 weeks of gestation, and that the earlier the infection occurs, the greater the risk to the fetus. However, there is considerable risk beyond the first trimester, up to the 24th week ([Hardy](#)).

Following the massive rubella epidemics of 1964 and 1965, the congenital rubella syndrome has been expanded to include low birth weight; sensorineural deafness, sometimes unilateral (the most common complication); microphthalmia; pigmentary degeneration of the retina (salt-and-pepper chorioretinitis); glaucoma, cloudy corneas, and cataracts of special type (the latter two abnormalities usually cause visual impairment); hepatosplenomegaly, jaundice, and thrombocytopenic purpura; and patent ductus arteriosus or interventricular septal defect. There may be one, a few, or many of these abnormalities, in various combinations. The mental retardation is severe and may be accompanied by seizures and motor defects such as hemiplegia or spastic diplegia and rarely by seizures. Psychiatric symptoms, some resembling autism, are not infrequent.

Infection of the fetus after the first trimester results in a less impressive neonatal syndrome. The infant may seem lethargic and fail to thrive. The cranium is abnormally small. Only a cardiac abnormality, deafness, or chorioretinitis may provide clues to the diagnosis. The CSF shows an increase of mononuclear cells and an elevated protein. The infection may persist for a year or longer. Foci of calcification are rare and CT scanning and MRI are of little help in diagnosis. The maternal infection may be so mild that it is passed off as minor; but even when it is evident, the fetus is spared in about 50 percent of cases. Diagnosis can be verified in the neonate by demonstrating IgM antibodies to the virus or by the isolation of the virus from the throat, urine, stool, or CSF. Also, the virus has been obtained from cells in the amniotic fluid.

The *neuropathology* is of considerable interest. In the nervous system of abortuses (the abortion performed because of proven maternal rubella in the first trimester), R. D. Adams found no visible lesions by light microscopy, even though the virus had been isolated from the brain by Enders. At this period of development there is no inflammatory reaction because of the absence of polymorphonuclear leukocytes, lymphocytes, and other mononuclear cells in the fetus. At birth the brain is usually of normal size, and there may be no discernible lesions. In a few, a mild meningeal infiltration of lymphocytes as well as a few zones of necrosis and vasculitis with later calcification of vessels are seen, as are small hemorrhages, presumably related to the thrombocytopenia. Smallness of the brain and delay in myelination have been observed in children dying at 1 to 2 years of age. None of the brains in our series have been malformed. Rubella virus continues to be recoverable from the CSF for at least 18 months after birth. A delayed progressive rubella encephalitis in childhood has also been described (page 811).

Since there is no treatment for the active infection, the obvious approach to the problem of congenital rubella infection is to make sure that every woman has been vaccinated against rubella or has had the infection prior to pregnancy. The widespread use of rubella vaccine has reduced the chance of major outbreaks, but sporadic infections continue to be seen, and outbreaks of epidemic proportions continue to occur in developing countries.

Cytomegalovirus Infection

For many years it was known that, in the tissues of some infants who died in the first weeks and months of life, there were swollen cells containing intranuclear and cytoplasmic inclusions. This cytologic change seemed related to the fatalities. In 1956 and 1957, three different laboratories isolated what has come to be called the *human cytomegalovirus*, or CMV (see [Weller](#)). This has proved to be the most frequent intrauterine viral infection.

Cytomegalovirus disease is caused by a DNA virus, a member of the herpes group, and is widespread in the general population. Although cervicitis is common, the virus is probably transmitted to the fetus transplacentally. Infection of the fetus usually occurs in the first trimester of pregnancy, sometimes later, by way of an inapparent maternal viremia and active infection of the placenta. The newborn can also be infected in the course of delivery or afterward by the mother's milk or by transfusions. However, only a small proportion of women known to harbor the virus give birth to infants with active infection. The likelihood of the fetus being infected is much greater if the seronegative mother becomes infected for the first time during pregnancy. Eighteen percent of infants born to such mothers were symptomatic at birth, and 25 percent became blind, deaf, or feebleminded within a few years ([Fowler et al](#)). In mothers with recurrent CMV infection, the infants were asymptomatic at birth, and only a few of them developed serious sequelae. Evidently, the presence of maternal antibodies before conception protects against congenital CMV infection.

Early infection of the fetus may result in a malformation of the cerebrum; later, there is only inflammatory necrosis in parts of the normally formed brain. In the low-birth-weight or full-term infant, the clinical picture is one of jaundice, petechiae, hematemesis, melena, direct hyperbilirubinemia, thrombocytopenia, hepatosplenomegaly, microcephaly, mental defect, and convulsions. Cells in the urine may show cytomegalic changes. There is a pleocytosis and an increased protein in the CSF. Disseminated inflammatory foci involve the cerebrum, brainstem, and retinae. In the centers of aggregates of lymphocytes, mononuclear cells, and plasma cells are microglial cells containing inclusion bodies; some astrocytes are similarly affected. The granulomas later calcify, particularly in the periventricular regions. Often there is hydrocephalus.

Congenital CMV infections pose a much greater problem than rubella. There is no way of identifying the infected fetus prior to birth or to prevent inapparent infections in the pregnant woman. As indicated above, if the pregnant woman has measurable titers of antibodies to CMV at the time of conception, her infant is relatively protected. Moreover, some infected infants (with viruria) may appear normal at birth but develop neural deafness and mental retardation several years later. Virus replication in infected organs continues after the first year and health workers are at risk. A second child may be infected.

There is no known treatment. The difficulties in prenatal diagnosis of maternal infection preclude planned abortion. Routine serologic testing should be done on every young woman of childbearing age. Until an effective vaccine becomes available, pregnancy should be avoided if a sexual partner is infected.

Childhood HIV Infection and AIDS

In the United States, about 10 percent of cases of acquired immunodeficiency syndrome (AIDS) have occurred in women, almost all of them of childbearing age, and the rate of new cases is increasing at a faster rate among them than among men. In children, practically all instances of AIDS come from an HIV-infected mother ("vertical transmission"). The infection may be acquired in utero, during delivery, or from breast feeding. The relative importance of each of these modes of transmission has not been settled.

It is estimated that HIV infection and AIDS occur in 15 to 30 percent of infants born to HIV-seropositive mothers (see [Prober and Gerson](#)). Infected infants present special difficulties in diagnosis, and the infection runs a more accelerated course in them than in adults. In the perinatal period, infected and noninfected infants can only rarely be distinguished clinically, and laboratory diagnosis is hampered by the presence of maternally derived antibody to HIV. The initial clinical signs usually appear within a few months after birth; practically all infected infants become ill before their first birthday, and very few are asymptomatic beyond 3 years of age. Early signs consist of lymphadenopathy, splenomegaly, hepatomegaly, failure to thrive, oral candidiasis, and parotitis. In the European Collaborative Study, comprising 600 children born to HIV-infected mothers, 83 percent of infected children showed laboratory or clinical features of HIV infection by 6 months of age. By 12 months, 26 percent had AIDS and 17 percent had died of HIV-related diseases. Once AIDS is established in children, it does not differ materially from the syndrome in adults ([Chap. 33](#)).

With reference to the involvement of the nervous system, there is often a delay in the attainment of psychomotor milestones. In others, after a period of normal development, a psychomotor decline begins, with corticospinal or peripheral nerve signs, often with pleocytosis. The typical giant-cell AIDS encephalitis, neuritis, and myelitis is easily distinguished from CMV encephalitis and toxoplasmosis.

Infected children are also subject to a variety of opportunistic infections, including bacterial meningitis, toxoplasmosis, CMV encephalitis, fungal infections (cryptococcosis, aspergillosis, candidiasis, herpes simplex and zoster, and mycobacterial meningitis). There may also be vascular lesions, with infarction or hemorrhage and lymphoid neoplasia. These are discussed in [Chap. 32](#) and [Chap. 33](#). There is little to be done for these children, but this may be changing with the current use of three-drug antiretroviral therapy, as described in [Chap. 33](#).

Toxoplasmosis

This tiny protozoan, *Toxoplasma gondii*, occurring freely or in pseudocyst form, is a frequent cause of meningoencephalitis in utero or in the perinatal period of life. The disease exists in all parts of the United States but is more frequent in western European countries, particularly in hot, humid climates. The mother is most often infected by exposure to cat feces, handling uncooked infected mutton or other meat, or eating partially cooked meat, but she is nearly always asymptomatic or has

only a mild fever and cervical lymphadenopathy.

The precise times of placental and fetal invasion are not known, but presumably they are late in the gestational period. The clinical syndrome usually becomes manifest in the first days and weeks of postnatal life, when seizures, impaired alertness, hypotonia, weakness of the extremities, progressive hydrocephalus, and chorioretinitis appear. The retinal lesions consist of large, pale areas surrounded by deposits of pigment. If the infection is severe, the maculae are destroyed; optic atrophy and microphthalmos follow. In older infants, we have several times observed hemiplegias, first on one side and then on the other, followed by hydrocephalus. The latter is present in about one-third of the cases. The CSF contains a moderate number of white blood cells, mostly lymphocytes and mononuclear cells, and the protein content is in the range of 100 to 400 mg/dL (i.e., a higher protein content than all other neonatal infections except bacterial meningitis). The glucose values are normal. Less than 10 percent of infected children recover; the others are mentally retarded, with seizures and paralysis. In those without symptoms of infection at birth, the outcome is better.

Granulomatous masses and zones of inflammatory necrosis about the ependyma and meninges. The organisms, 6 to 7 mm in length and 2 to 4 mm in width, are visible in and near the lesions. Microcysts may also be found, lying free in the tissues without surrounding inflammatory reaction. The necrotic lesions calcify rapidly and, after several weeks or months, are readily visible in plain films of the skull. These appear in periventricular and other regions of the brain as multiple nodular densities.

In adults, mainly in patients with AIDS, the disease takes the form of a rapidly evolving meningitis and multifocal encephalitis in conjunction with myocarditis, hepatitis, and polymyositis. This syndrome is described on page 775, as are the diagnostic tests and treatment. In the infant, infections such as rubella, syphilis, CMV disease, and herpes simplex must be considered in the differential diagnosis. The most reliable means of diagnosis is the IgM indirect fluorescent antibody test, performed on umbilical cord blood. Passive transfer of IgG antibody from mother to fetus takes place, but its presence in the latter is not proof of active infection.

In women who develop antibodies in the first 2 or 3 months of pregnancy, treatment with spiramycin (Rovamycin) prevents fetal infection. Once the fetus is infected, pyrimethamine and sulfadiazine must be used. A later second pregnancy is not affected.

Congenital Neurosyphilis

The clinical syndromes and pathologic reactions of congenital neurosyphilis of the newborn are similar to those of the adult, as described on pages 762 to 768. Such differences as exist are determined principally by the immaturity of the nervous system at the time of spirochetal invasion.

The syphilitic infection may be transmitted to the fetus at any time from the fourth to the seventh months. The fetus may die, with resulting miscarriage or stillbirth, or may survive only to be born with florid manifestations of secondary syphilis. The dissemination of the spirochetes throughout the body, the time of appearance of the secondary manifestations, and the time of formation of antisyphilitic antibodies (reagin) in the blood are all governed by the same biologic principles that apply to adult syphilis.

At birth the spirochetemia may not have had time to cause syphilitic reagin or antibodies to appear; hence a negative Venereal Disease Research Laboratories (VDRL) reaction in umbilical cord blood does not exclude syphilis. In unselected groups of syphilitic mothers, 25 to 80 percent of fetuses are infected, and in 20 to 40 percent of those infected, the CNS is invaded, as judged by the finding of abnormal CSF. The types of congenital neurosyphilis (asymptomatic and symptomatic meningitis, meningovascular disease, hydrocephalus, general paresis, and tabes dorsalis) are the same as those in the adult except for the great rarity of tabes dorsalis. The Hutchinson triad (dental deformities, interstitial keratitis, and bilateral deafness) is infrequently observed in complete form. The sequence of neurologic syndromes is also the same as in the adult, all stemming basically from a chronic spirochetal meningitis. The latter may become symptomatic in the first weeks and months of postnatal life, meningovascular lesions and hydrocephalus reaching maximal frequency during the 9-month to 6-year period; congenital paresis and tabes usually appear between the ninth to fifteenth years. The pathologic basis of each neurosyphilitic syndrome is, respectively, meningoarteritis (vascular syphilis), meningoencephalitis (general paresis), and meningoradiculitis (tabes dorsalis).

All neurologists have observed fewer and fewer cases of congenital neurosyphilis as the years pass, but there may be a recrudescence of the disease. If the syphilitic mother is treated before the fourth month of pregnancy, the fetus will not be infected. The infant may be normal at birth or exhibit only mucocutaneous lesions, hepatosplenomegaly, lymphadenopathy, and anemia. There are in the neonatal period no signs of meningeal invasion, or there may be only an asymptomatic meningitis. If the latter is actively treated until the CSF is normal, vascular lesions of brain and spinal cord, hydrocephalus, general paresis, and tabes dorsalis will not develop. If cases of meningovascular syphilis, general paresis, and tabes dorsalis are treated for 3 to 4 weeks with penicillin until the CSF is rendered acellular and the protein reduced to normal, the neurologic disorder will be arrested and often there is functional improvement.

The various neurosyphilitic syndromes are described fully in [Chap. 32](#), as mentioned above.

Congenital syphilis must be considered a potential albeit rare cause of epilepsy and mental retardation. Once the syphilitic infection has been treated in early life and rendered inactive (acellular CSF, normal protein), the occurrence of a congenital luetic infection can only be substantiated by an accurate history; the finding of the syphilitic stigmata in the eyes, teeth, and ears; or a positive serologic reaction in the CSF.

Treatment of syphilis in the child follows along the same lines as treatment of the syphilitic adult (page 767), with appropriate adjustment of dosage in accordance with the child's weight.

Other Viral and Bacterial Infections

Several other infections of late fetal life or the neonatal period are only mentioned here, for to describe them all would be tedious and would elucidate no new neurologic principles. Meningitis due to the small gram-positive rod *Listeria monocytogenes* may be acquired in the usual way, at the time of passage through an infected birth canal or in utero, as a complication of maternal and fetal septicemia due to this organism. In the latter case, it causes abortion or premature delivery. Neonatal meningitis is a particularly devastating and often fatal type of bacterial infection, not easily diagnosed unless the pediatrician is alert to the possibility of a silent meningitis in every case of neonatal infection (page 740).

Herpes simplex virus (HSV) encephalitis may destroy large parts of the brain, particularly of the temporal lobes, and is frequently fatal. Coxsackie B, polioviruses, other enteroviruses, and arboviruses (western equine) seem to be able to cross the placental barrier late in pregnancy and cause encephalitis or encephalomyelitis in the fetus at term—indistinguishable from the disease in the very young infant.

Epstein-Barr virus is another and not infrequent cause of meningoencephalitis. In some instances it may present as an aseptic meningitis or a Guillain-Barré type of acute polyneuritis. This infection is more apt to affect the nervous system of children than that of adults. It is estimated that approximately 2 percent of children and adolescents with this infection have some type of neurologic dysfunction; rarely this will be the only manifestation of the disease. Stupor, chorea, and aseptic meningitis were the main neurologic findings in the case reported by [Friedland and Yahr](#), and acute cerebellar ataxia and deafness in the case of Erzurum and associates (see also [Chap. 32](#) and [Chap. 33](#)). Herpes zoster may occur in utero, leaving cutaneous scars and retarding development. Or zoster may appear soon after birth, the infection having been contracted from the mother. Later in childhood, varicella may induce an autoimmune perivenous demyelination and possibly a direct infection, affecting predominantly the cerebellum (pages 797 and 977), or the now rare Reye syndrome.

EPILEPSIES OF INFANCY AND CHILDHOOD

The major types of seizure disorder have already been discussed in some detail in [Chap. 16](#). In bringing them up again here, attention is drawn to the fact that epilepsy is mainly a disease of infancy and childhood. Approximately 75 percent of epileptics fall into these age periods, and some of the most interesting and unique types of seizure are peculiar to these epochs of life. Epilepsies that are observed exclusively in infants and children are benign neonatal convulsions, benign myoclonic epilepsy of infancy, febrile seizures (both genetic and acquired), infantile spasms of West, absence seizures, the Lennox-Gastaut syndrome, rolandic and occipital paroxysms and other benign focal epilepsies, and the juvenile myoclonic epilepsies.

One principle that emerges is that the form taken by seizures in early life is in part age-linked. Neonatal seizures are predominantly partial or focal; infantile seizures take the form of myoclonic flexor (sometimes extensor) spasms; and the various forms of petit mal are essentially diseases of childhood (4 to 13 years). The motor phenomena of epilepsy in young children are often termed *myoclonic*, but this should not be confused with other, later-occurring epilepsies that are endowed with the

same name. Further, certain epileptic states tend to occur during certain epochs of life—one type of febrile seizures from 6 months to 6 years and generalized or temporal spike-wave activity with benign motor and complex partial seizures from 6 to 16 years, and juvenile myoclonic epilepsy in the mid- and late-adolescent years. In general, idiopathic epilepsy, so called because the cause cannot be determined, is predominantly a pediatric neurologic problem. This is not to say that seizures of unknown cause do not occur for the first time in adult life but rather that the onset of such seizures is far more frequent in childhood and tends to diminish once adulthood is reached.

The clinical characteristics of infantile and childhood seizures are fully described in [Chap. 16](#).

MORE SEVERE FORMS OF MENTAL RETARDATION

The subject of mental retardation was introduced in [Chap. 28](#), where it was pointed out that two major categories of this disorder have been delineated. In one, and by far the more common group, the mental retardation is relatively mild, allowing the individual to benefit from training and education; it is often familial (called subcultural) and is featured by a lack of definite neurologic abnormalities (except possibly a slightly higher incidence of seizures) and the absence of neuropathologic changes. A large part of this group, falling between 2 and 3 standard deviations from the normal mean IQ, probably are the lower end of the Gaussian curve of intelligence, the converse of which is genius. In the second group, the degree of mental retardation is usually more severe, most are nonfamilial, and a wide variety of neuropathologic changes are in evidence. The division is not absolute, for there are a few metabolic and developmental diseases in which mental retardation is profound, but with no somatic or neurologic abnormalities and no well-defined neuropathologic changes—e.g., Rett syndrome, autism, and the X-linked mental retardation syndromes such as the Renpenning and fragile-X types. In this chapter only these major types of *severe mental retardation* are described.

The overall frequency of severe mental retardation cannot be stated precisely. Rough estimates would place the figure at 0.2 to 0.4 percent of the general population and at about 10 percent of the retarded segment of society. It is important to emphasize that severe mental retardation in a large proportion of individuals can presently not be traced to particular congenital anomalies of development or to any of the disorders reviewed in the preceding pages. When groups of such severely retarded patients are *studied clinically, a reasonably accurate etiologic determination of the underlying brain disease can be made in only slightly more than half of them*. According to Penrose, chromosome abnormalities account for 15 percent, single-gene disorders for 7 percent, and environmental agents for 20 percent. Recent studies of the subtelomeric parts of chromosomes reportedly find abnormalities in another 7 percent of severely retarded children ([Knight et al](#)). No cause is found for the remaining cases. Males outnumber females 3:1. For purposes of comparison, our figures, obtained from a study of 1372 patients at the Walter E. Fernald School, are presented in [Table 38-3](#).

Disease category	Number of patients		Percent of all patients
	IQ<50	IQ>50	
Acquired destructive lesions	278	79	26.0
Chromosomal abnormalities	247	10	18.7
Multiple congenital anomalies	64	16	5.8
Developmental abnormality of brain	49	16	4.7
Metabolic and endocrine diseases	38	5	3.1
Progressive degenerative disease	5	7	0.9
Neurocutaneous diseases	4	0	0.3
Psychosis	7	6	1.0
Mentally retarded (cause unknown)	385	156	39.5

Table 38-3 Causes of severe and mild mental retardation in 1372 patients at the W. E. Fernald State School

From the neuropathologic standpoint, *the examination of the brains of the severely retarded by conventional histopathologic methods discloses lesions in approximately 90 percent, and in fully three-quarters an etiologic diagnosis can be determined*. Many of the remaining 10 percent of the “pathologically retarded” actually lack definite pathologic changes, but their brains are lighter in weight by 10 to 15 percent than age-matched normal brains. Interestingly, the proportion of vascular, hypoxic-ischemic, metabolic, and genetic lesions in this group of severely retarded is much the same as is found in a group selected on the basis of “cerebral palsy.”

Here it is important to repeat a point made earlier and in [Chap. 28](#), that a few of the severely disabled and a large majority of the mildly retarded do not have a recognizable cerebral pathology or exhibit any of the familiar and conventional signs of cerebral disease. Although the milder forms of mental retardation tend to be familial, this does not by itself separate them from the severe forms of mental retardation. There are several types of hereditary mental retardation, in which the retardation may be severe and in some of which there may be maldevelopment of the cerebral cortex. These are discussed further on.

Clinical Characteristics of the Severely Retarded

In one large group of severely retarded, designated the *dysmorphic retardates*, a variety of physical deformities, particularly microcephaly, is common. In a second group, *multiple system retardation*, the mental retardation is linked to nonskeletal abnormalities (hepatosplenomegaly as well as hematologic and skin disorders), which provide reliable clues to the underlying somatic disease. In a third group, the *neurologic retardates*, somatic abnormalities are lacking; the configuration of neurologic signs often leads to the diagnosis. And in a fourth and most difficult group, the *uncomplicated retardates*, there are no or minimal somatic, visceral, and neurologic abnormalities. One is then forced to turn to special features of the mental retardation itself for identification of the underlying disease. [Table 38-4](#) elaborates our classification of the types of mental retardation.

3. Dysmorphic defect with somatic developmental abnormality (neurocutaneous syndrome) A. Those affecting craniofacial structure 1. Microcephaly 2. Hydrocephalus (including arachnoid cysts) 3. Craniofacial anomalies (including cleft lip and palate, cleft palate, and associated cranial anomalies) 4. Bone dysplasia 5. Connective tissue dysplasia (Marfan's, Ehler's) 6. Musculoskeletal disorders (osteitis, rickets, and bone marrow defects) 7. Anomalous dentition (malocclusion and other craniofacial abnormalities) 8. Anomalous eyelids (epicanthic folds, cataracts, and other eye defects) 9. Bone growth retardation (Osteogenesis imperfecta, osteoporosis, and other bone diseases) 10. Deafness, other sensory defects (deafness, blindness, and other sensory defects) 11. Deafness, blindness, and other sensory defects (deafness, blindness, and other sensory defects) 12. Deafness, blindness, and other sensory defects (deafness, blindness, and other sensory defects) 13. Deafness, blindness, and other sensory defects (deafness, blindness, and other sensory defects) 14. Deafness, blindness, and other sensory defects (deafness, blindness, and other sensory defects) 15. Deafness, blindness, and other sensory defects (deafness, blindness, and other sensory defects) 16. Deafness, blindness, and other sensory defects (deafness, blindness, and other sensory defects) 17. Deafness, blindness, and other sensory defects (deafness, blindness, and other sensory defects) 18. Deafness, blindness, and other sensory defects (deafness, blindness, and other sensory defects) 19. Deafness, blindness, and other sensory defects (deafness, blindness, and other sensory defects) 20. Deafness, blindness, and other sensory defects (deafness, blindness, and other sensory defects) 21. Deafness, blindness, and other sensory defects (deafness, blindness, and other sensory defects) 22. Deafness, blindness, and other sensory defects (deafness, blindness, and other sensory defects) 23. Deafness, blindness, and other sensory defects (deafness, blindness, and other sensory defects) 24. Deafness, blindness, and other sensory defects (deafness, blindness, and other sensory defects) 25. Deafness, blindness, and other sensory defects (deafness, blindness, and other sensory defects) 26. Deafness, blindness, and other sensory defects (deafness, blindness, and other sensory defects) 27. Deafness, blindness, and other sensory defects (deafness, blindness, and other sensory defects) 28. Deafness, blindness, and other sensory defects (deafness, blindness, and other sensory defects) 29. Deafness, blindness, and other sensory defects (deafness, blindness, and other sensory defects) 30. Deafness, blindness, and other sensory defects (deafness, blindness, and other sensory defects) 31. Deafness, blindness, and other sensory defects (deafness, blindness, and other sensory defects) 32. Deafness, blindness, and other sensory defects (deafness, blindness, and other sensory defects) 33. Deafness, blindness, and other sensory defects (deafness, blindness, and other sensory defects) 34. Deafness, blindness, and other sensory defects (deafness, blindness, and other sensory defects) 35. Deafness, blindness, and other sensory defects (deafness, blindness, and other sensory defects) 36. Deafness, blindness, and other sensory defects (deafness, blindness, and other sensory defects) 37. Deafness, blindness, and other sensory defects (deafness, blindness, and other sensory defects) 38. Deafness, blindness, and other sensory defects (deafness, blindness, and other sensory defects) 39. Deafness, blindness, and other sensory defects (deafness, blindness, and other sensory defects) 40. Deafness, blindness, and other sensory defects (deafness, blindness, and other sensory defects) 41. Deafness, blindness, and other sensory defects (deafness, blindness, and other sensory defects) 42. Deafness, blindness, and other sensory defects (deafness, blindness, and other sensory defects) 43. Deafness, blindness, and other sensory defects (deafness, blindness, and other sensory defects) 44. Deafness, blindness, and other sensory defects (deafness, blindness, and other sensory defects) 45. Deafness, blindness, and other sensory defects (deafness, blindness, and other sensory defects) 46. Deafness, blindness, and other sensory defects (deafness, blindness, and other sensory defects) 47. Deafness, blindness, and other sensory defects (deafness, blindness, and other sensory defects) 48. Deafness, blindness, and other sensory defects (deafness, blindness, and other sensory defects) 49. Deafness, blindness, and other sensory defects (deafness, blindness, and other sensory defects) 50. Deafness, blindness, and other sensory defects (deafness, blindness, and other sensory defects) 51. Deafness, blindness, and other sensory defects (deafness, blindness, and other sensory defects) 52. Deafness, blindness, and other sensory defects (deafness, blindness, and other sensory defects) 53. Deafness, blindness, and other sensory defects (deafness, blindness, and other sensory defects) 54. Deafness, blindness, and other sensory defects (deafness, blindness, and other sensory defects) 55. Deafness, blindness, and other sensory defects (deafness, blindness, and other sensory defects) 56. Deafness, blindness, and other sensory defects (deafness, blindness, and other sensory defects) 57. Deafness, blindness, and other sensory defects (deafness, blindness, and other sensory defects) 58. Deafness, blindness, and other sensory defects (deafness, blindness, and other sensory defects) 59. Deafness, blindness, and other sensory defects (deafness, blindness, and other sensory defects) 60. Deafness, blindness, and other sensory defects (deafness, blindness, and other sensory defects) 61. Deafness, blindness, and other sensory defects (deafness, blindness, and other sensory defects) 62. Deafness, blindness, and other sensory defects (deafness, blindness, and other sensory defects) 63. Deafness, blindness, and other sensory defects (deafness, blindness, and other sensory defects) 64. Deafness, blindness, and other sensory defects (deafness, blindness, and other sensory defects) 65. Deafness, blindness, and other sensory defects (deafness, blindness, and other sensory defects) 66. Deafness, blindness, and other sensory defects (deafness, blindness, and other sensory defects) 67. Deafness, blindness, and other sensory defects (deafness, blindness, and other sensory defects) 68. Deafness, blindness, and other sensory defects (deafness, blindness, and other sensory defects) 69. Deafness, blindness, and other sensory defects (deafness, blindness, and other sensory defects) 70. Deafness, blindness, and other sensory defects (deafness, blindness, and other sensory defects) 71. Deafness, blindness, and other sensory defects (deafness, blindness, and other sensory defects) 72. Deafness, blindness, and other sensory defects (deafness, blindness, and other sensory defects) 73. Deafness, blindness, and other sensory defects (deafness, blindness, and other sensory defects) 74. Deafness, blindness, and other sensory defects (deafness, blindness, and other sensory defects) 75. Deafness, blindness, and other sensory defects (deafness, blindness, and other sensory defects) 76. Deafness, blindness, and other sensory defects (deafness, blindness, and other sensory defects) 77. Deafness, blindness, and other sensory defects (deafness, blindness, and other sensory defects) 78. Deafness, blindness, and other sensory defects (deafness, blindness, and other sensory defects) 79. Deafness, blindness, and other sensory defects (deafness, blindness, and other sensory defects) 80. Deafness, blindness, and other sensory defects (deafness, blindness, and other sensory defects) 81. Deafness, blindness, and other sensory defects (deafness, blindness, and other sensory defects) 82. Deafness, blindness, and other sensory defects (deafness, blindness, and other sensory defects) 83. Deafness, blindness, and other sensory defects (deafness, blindness, and other sensory defects) 84. Deafness, blindness, and other sensory defects (deafness, blindness, and other sensory defects) 85. Deafness, blindness, and other sensory defects (deafness, blindness, and other sensory defects) 86. Deafness, blindness, and other sensory defects (deafness, blindness, and other sensory defects) 87. Deafness, blindness, and other sensory defects (deafness, blindness, and other sensory defects) 88. Deafness, blindness, and other sensory defects (deafness, blindness, and other sensory defects) 89. Deafness, blindness, and other sensory defects (deafness, blindness, and other sensory defects) 90. --	---

evidenced by psychomotor delay and a failure to speak by the second or third postnatal year. The patient does not acquire the usual household and play activities as well as other children. However, delay in speech development must not, by itself, be taken as a mark of mental retardation, for in some children a unique delay in speech can be an isolated abnormality (see [Chap. 28](#)), with subsequent normal development of speech. Toilet training may be difficult to accomplish in the retarded child, but, again, bed wetting may be a problem in an otherwise normal child. Also, the deaf child may have to be considered separately; the problem becomes apparent by an indifference to noise and reduced vocalization (stereotypy of babbling).

More searching analyses of cognitive functions in the moderately retarded child have been undertaken by O'Connor and Hermelin, by [Pulsifer](#), and by others. These authors have attempted to measure efficiency of visual and auditory perception, adequacy of communication, relations between language development and thought, cross-modal sensory encoding, alertness, attention, and memory. It was concluded that none of these functions was specifically impaired. Instead, the retarded child could not properly encode new information because the memory systems and stock of assimilated knowledge were insufficient to provide a framework of items and categories with which new information could be integrated. Some also seem unable, perhaps because of this, to extract from perceived material selective features that can be interpreted. Further, they were unable to deal with an array of sensory experiences like normal children. The complexity of these operations, which the authors would reduce to a global failure of the normal processes of apperception and integration, has been called by [Piaget](#) a failure of assimilation and accommodation. This type of inadequacy is common to many different diseases, but in each one there are other subtle differences not yet fully analyzed by neuropsychologists.

Within the spectrum of mental retardation, apart from cognitive impairments, there are differences in behavior and personality, even in those with more or less the same IQ. Some moderately severe retardates are pleasant and amiable and achieve a rather satisfactory social adjustment. This is particularly notable in patients with Down and Williams syndromes. At the opposite end of the behavioral scale is the syndrome of autism, in which the individual fails to manifest normal interpersonal social contact, including communicative language. The phenylketonuric retardate is usually irritable, unaffectionate, and implacable, and the same is said of other retardates, such as those with the DeLange syndrome, discussed earlier in the section on retardation with dwarfism.

Regarding activity levels, many retarded individuals are slow, clumsy, and relatively akinetic. Others, as many as half of them, display an incessant hyperactivity characterized by a restless, seemingly inquisitive searching of the environment. When thwarted, they have a low frustration tolerance. They may be destructive and recklessly fearless and impervious to the risk of injury. Some exhibit a peculiar anhedonia that renders them indifferent to both punishment and reward. Other aberrant types of behavior, such as violent aggressiveness and self-mutilation, are common. Rhythmic rocking, head banging, incessant arm movements—so-called rhythmicias or movement stereotypies—are observed in the majority of severe retardates. They are maintained hour after hour without fatigue and may be accompanied by breathing sounds, squeals, and other exclamations. Self-stimulation, even hurtful—such as striking the forehead or ears or biting the fingers and forearms—seems compulsive or perhaps provides satisfaction. It is not that these rhythmicias are by themselves abnormal, for some of them occur for brief periods in normal babies, but that they persist. Some moderately retarded persons, when assigned to a simple task such as putting envelopes in a box, can continue this activity under supervision for several hours.

It is impossible to list all the varieties of mental retardation here; the point to be made is that all aspects of intellectual life, personality, and deportment are affected in differing degrees and that these effects have a neurologic basis. There is more than a hint that in particular diseases, because of their anatomy, the cognitive experience, affective life, and behavior are affected in special ways. The group of moderately retarded, like the severely retarded, is divisible into groups with somatic systemic and neurologic abnormalities, though the proportions are not the same. There are fewer of the dysmorphic type and more of the nondysmorphic, nonneurologic group.

Etiology of Severe Mental Retardation From [Table 38-3](#) it is obvious that many diseases can blight the development and maturation of the brain, leaving it in an arrested state. Some of them are acquired and some are congenital and hereditary. Some affect all parts of the organism, giving rise to associated dermal, skeletal, and visceral abnormalities, while others affect only the nervous system in particular patterns. With respect to the *milder degrees of mental retardation*, in all populations thus far studied, extreme low-birth-weight infants are more likely to have disabilities, brain abnormalities, and poorer language development and scholastic achievement. This correlates with lower social status, which must relate in some manner to biological factors (Scottish Low-Birth-Weight Study). Viral and spirochetal infections and parturitional accidents are common causes. They act acutely and are theoretically preventable. The factor of malnutrition during the fetal or infantile period of life as a cause of severe mental retardation has received considerable attention because it is worldwide. Animal experiments (by [Winick](#) and others) have demonstrated that severe undernutrition in early life leads to behavioral abnormalities and biochemical and morphologic changes in the brain, which may be permanent (see [Chap. 41](#)). Galler studied a group of infants in Barbados who were malnourished during the first year of life and then given an adequate diet. These children were followed to adulthood and compared with normally nourished siblings. Galler observed no effect on physical growth, but there were persistent attention deficits in 60 percent of the undernourished group and in only 15 percent of controls. The IQ scores of the former were also lower. Unfortunately, genetic factors were not completely controlled. In general, it may be said that the data showing mental retardation to be caused by malnutrition, while suggestive, are far from convincing.

Severe protein-calorie malnutrition in the first 8 months of life, which induces kwashiorkor, does seem to retard mental development. However, such patients are said to regain mental function when fed. The authors have been impressed with the ability of the nervous system to withstand the effects of nutritional deficiency, perhaps better than any other organ.

The action of exogenous toxins during pregnancy is another factor to be considered. Severe maternal alcoholism has been linked to a dysgenetic syndrome, including mental retardation, but the findings of several studies have not been consistent (see [Chap. 42](#)). Surprisingly, maternal addiction to opiates, while causing an opiate withdrawal in infants for weeks or even months ([Wilson et al](#)), seems not to result in permanent injury to the nervous system. The exposure to small amounts of environmental lead is also controversial.

The effect of psychologic deprivation has been of interest. Following the observations that complete isolation of young female monkeys had a devastating effect on their later sexual and nurturing behavior, the idea became popular that sensory deprivation might cause faulty mental development in humans. Orphaned and neglected babies were found to be inactive, apathetic, and backward in comparison with those who were constantly stimulated by caring mothers. But surprisingly, when nurtured properly at a later time, these babies soon caught up with their peers. This general idea of psychologic deprivation was the basis of many interesting head-start programs for poor and neglected children. To this day, however, it has not been proven that sensory, emotional, and psychologic deprivations are the causes of severe mental retardation or repeated scholastic failure. However, the problem is a complex one, and the arguments pro and con have been carefully elaborated by [Haywood and Wachs](#). The controversies regarding the effects of prematurity, maternal hypertension, and eclampsia, which are often associated with retarded psychomotor development, were described earlier in this chapter.

The genetic types of severe mental retardation, including the novel type associated with subtelomeric abnormalities, have already been mentioned.

Differentiation of Types of Retardation: Clinical Approach

As a particular guide to the pediatrician and neurologist who must assume responsibility for the diagnosis and management of backward children harboring a wide array of diseases and maldevelopments of the nervous system, the following clinical approach is suggested. First, as already described, there is an advantage in setting aside as one large group those who are only mildly retarded from those who have been severely delayed in psychomotor development since early life. With regard to the former group, having no obvious neurologic signs or physical stigmata, the only medical problems they present are in the spheres of behavioral, educational, and psychosocial adjustments. One should nevertheless initiate a search for the common metabolic, chromosomal, and infective diseases. In this large group one must be sure that their deficit is a general one and not one of hearing, poor sight, or the special language and attention deficits described in [Chap. 23](#) and [Chap. 28](#).

For patients with the moderately severe and very severe deficits, one begins always with a careful physical examination, searching for somatic stigmata and neurologic signs. Abnormalities of eyes, nose, lips, ears, fingers, and toes are particularly important, as are a variety of neurologic abnormalities, as outlined in [Table 38-4](#). Data so obtained allow classification into one of three categories, as follows.

In one group, *those with somatic abnormalities* (with or without obvious neurologic signs), one assumes the presence of a maldevelopment of the brain, possibly caused by a chromosomal abnormality. The psychomotor retardation is usually severe and often nongenetic and, as a rule, has a well-defined neuropathology. Diagnosis is determined by the gestalt of physical signs. The possible maldevelopments are numerous and diverse and have been summarized in [Table 38-1](#) and [Table 38-4](#); some of the main ones have been described earlier in the chapter. One inevitably turns to the several atlases to denominate the syndromes ([Holmes et al; Jones](#)).

In the second group, in which the *abnormalities are confined to the nervous system*, attention is focused on a larger number of diseases, many due to exogenous

factors such as perinatal hypoxia-ischemia, pre- or postnatal infections, trauma, and so on. There are usually conspicuous neurologic signs. The degree of mental retardation is variable, depending on the location and extent of a demonstrable neuropathology. Usually the family history is negative, but careful questioning of parents regarding the pregnancy, delivery, and early postnatal period, and examination of older hospital records may disclose the nature of the neurologic insult.

The third category of retardates is one in which *neither somatic anomalies nor focal neurologic signs* are present. The more severely retarded of this third group are represented by the following disease states: autism (Asperger-Kanner syndrome), the Rett and Williams syndromes, and the fragile-X and Renpenning syndromes. The last three have a genetic basis and are described together below.

The practical importance of this clinical approach is that it directs the intelligent use of laboratory procedures for confirmation of the diagnosis. CT scanning and MRI are useful in clarifying maldevelopment and neurologic diseases but are seldom helpful in the third group. EEG confirms seizure discharges when there is uncertainty as to the nature of episodic neural dysfunction. Karyotyping and genetic studies are useful in group 1 and rarely in group 2 patients.

The major pitfall to be avoided in this clinical approach is in mistaking a hereditary metabolic disease for a developmental one. Here one is helped by the fact that manifestations of the metabolic diseases are not usually present in the first days and weeks of life; they appear later and are progressive and often associated with visceral abnormalities. However, some metabolic diseases are of such slow progression that they appear stable, especially the late-onset ones, such as one type of metachromatic leukodystrophy, late-onset Krabbe leukodystrophy, adult adrenoleukodystrophy, and adult hexoseaminidase deficiency (see [Chap. 37](#)).

Hereditary Mental Retardations

Fragile-X Syndrome There is now great interest in this syndrome, which some geneticists hold accountable, at least in part, for the preponderance of males among institutionalized retarded individuals. The subject is discussed earlier in this chapter, particularly as it relates to other chromosomal abnormalities (page 1067). A large kindred in which mental retardation was inherited in an X-linked pattern was first reported by [Martin and Bell](#) in 1943. It was in such a family, with X-linked mental retardation, that Lubs, in 1969, discovered a fragile site at the distal end of the long arm of the X chromosome; subsequently it was established that there is an unstable inherited CGG repeating sequence at this site, as discussed previously.

Fully 10 percent of mentally retarded males have this fragile X chromosomal abnormality. Females are sometimes affected, but their mental function is only slightly reduced. Affected males have only mild dysmorphic features (large ears, broad forehead, elongated face, and enlarged testes) that may not become obvious until puberty. Others are somatically normal. Behavioral problems of one sort or another are almost universal. Pulsifer, whose review of the neuropsychologic aspects of mental retardation is recommended, lists self-injurious, hyperactive, and impulsive behaviors as the most common. The hand flapping that is characteristic of autism may also be seen.

Renpenning Syndrome A similar type of hereditary, male sex-linked mental retardation has been described by [Renpenning](#). The family comprised 21 males in two generations of Mennonites in western Canada whose IQs ranged from 30 to 40. As with the fragile-X syndrome, female siblings may show slight degrees of retardation. Affected members were small in stature and slightly microcephalic but otherwise free of somatic and neurologic abnormalities. They did not have the fragile-X abnormality.

Rett Syndrome This is yet another hereditary form of mental retardation, but affecting only girls. None of the cases reported by [Hagberg](#) and coworkers were male. Recently the responsible spontaneous mutation has been shown to be a dominant defect at chromosomal site Xq28. A fatal outcome in boys explains the expression of the disease only in girls, who are mosaics for the mutation. The involved gene, MECP2, is responsible for suppressing various other genes at critical stages of development.

The syndrome is characterized clinically by withdrawn behavior that simulates autism, dementia, ataxia, loss of purposeful hand movements, and respiratory irregularities, all of which appear and progress after a period of 6 to 18 months of normal development. Spasticity, muscle wasting, scoliosis, and lower limb deformities may become evident in late stages of the illness. Hand waving, hand wringing, and similar stereotypes are very characteristic features (and are subtly different from the hand flapping of autistic children).

Armstrong and Naidu, who have reviewed the neuropathology, have drawn attention to a number of subtle cortical abnormalities, most of which are consistent with disruption of the dynamic phase of brain development postnatally; however, not all cases showed these abnormalities. While most cases appear to be sporadic, there is a high familial incidence and concordance in twins. However, this is still a matter of contention.

Williams Syndrome This inherited form of mental retardation has also been mentioned earlier, on page 1068, in relation to the chromosomal abnormalities. It is characterized by only mild mental retardation but with striking retention and even precocity of musical aptitude, social amiability, and in some instances a retained facility for writing, permitting the production of long written descriptions; at the same time these subjects are barely able to draw simple objects. The child is physically retarded and has minor but distinctive somatic changes (wide mouth, almond-shaped eyes, upturned nose, small pointed ears), together described as “elfin.” He is usually sensitive to auditory stimuli. There is a delay in the acquisition of communicative speech and defects in visual, spatial, and motor skills, making these children seem more backward than they actually are. Striking sociability and empathy sets them apart; they represent virtually the converse of autism in this respect. Memory for musical scores—such as memorizing a complete symphony after one hearing—may be prodigious. By the use of high-resolution cytogenetics, the disease has been traced in 90 percent of cases to a microdeletion on chromosome 7 in the region of the gene that controls the production of elastin ([Nickerson et al](#)). This is of interest because an index feature of these cases is a supravalvular aortic stenosis. It is not known whether there is a characteristic brain pathology, but a recent case of Golden and colleagues, examined at 35 years of age, showed no cerebral abnormalities except for Alzheimer changes, mainly plaque deposition in the entorhinal cortex and amygdala.

Autism (Kanner-Asperger Syndrome; Autistic Spectrum Disorders)

This condition was described almost simultaneously by [Kanner](#) in Baltimore (in 1943) and [Asperger](#) in Vienna (in 1944). Among the large group of retarded children, Kanner observed exceptional children who appeared to be *asocial, lacking in communicative skills both verbal and nonverbal, and committed to repetitive ritualistic behaviors*. At the same time certain intellectual capacities—such as retentive memory, skilled sensory and motor aptitudes, and capacity for visual spatial perception—were retained. In other words, the disorder did not pervade all aspects of mental development. It is the gestalt of negative and positive aptitudes that sets this syndrome apart from other types of retardation. Kanner incorrectly ascribed the condition to psychosocial factors—such as a cold, aloof parent—and regarded it as an autistic psychopathy. The implication that these children are literally “autistic”—i.e., that they have a rich inner psychic life or dream world out of relation to reality—is an assumption wholly without foundation. Asperger, whose observations included somewhat older children, less completely disabled, ascribed it to a special metabolic disease, possibly related to hyperammonemia. Opinion varied as to the relationship between the severe Kanner syndrome and the less severe Asperger syndrome. The authors have taken the position that these forms of autism represent a single syndrome of varying severity, with similar pathologic underpinnings but possibly of multiple etiologies, including genetic.

For reasons mentioned above, the term *autism*, drawn from psychiatry, is inappropriate but is firmly embedded in the medical lexicon. Despite many claims to the contrary, there is absolutely no evidence of a psychogenesis. However, as Rapin points out, behavioral modification and special education are beneficial for the less severely affected. At one time the disorder was referred to as childhood schizophrenia, but the afflicted individuals do not resemble schizophrenics, even when they reach adult years. The very early onset (preschool) onset of autism, the lack of delusional thinking, and different inheritance patterns are other points against this being a type of childhood schizophrenia. Moreover, the manifestations of autism change to some extent in the course of development—a characteristic of what is called, for lack of a better label, a neurodevelopmental disorder.

The overall prevalence of the autistic state has been calculated at 4.5 to 20 per 10,000. Although there is said to be no familial tendency to autism, this is almost certainly incorrect; we have seen the disease in both of identical twins and in brothers, and a small familial subgroups are known to exist. Autistic traits, without the full syndrome, are being found with increasing frequency in sibs and other family members, suggesting a polygenic inheritance. DeMyer found that 4 out of 11 monozygotic twins were concordant for autism and that siblings have a 50 times greater risk of developing the disorder. Bailey and also LeCouteur and associates have reported a concordance rate in monozygotic twins of 71 percent for the autistic spectrum disorder and 92 percent for an even broader phenotype of disordered social communication and stereotypic or obsessive behaviors. DeLong finds a surprisingly high incidence of manic-depressive disease in the families of one group of autistic children.

Clinical Features The autistic child is ostensibly normal at birth and may continue to be normal in achieving early behavioral sequences until 18 to 24 months of age.

Then an alarming regression occurs. In some instances, however, the abnormality appears even before the first birthday and is identified as different from normal by the mother; or, if there had been a previously autistic child, she recognizes the early behavioral characteristics. The level of activity is reduced or increased. There may be less crying and an apparent indifference to surroundings. Toys are ignored or held tenaciously. Cuddling may be resisted. Motor developments, on the other hand, proceed normally and may even be precocious. Later there may be an unusual sensitivity to all modes of sensory stimulation. Occasionally the onset appears to have a relationship to an injury or an upsetting experience.

Regardless of the time of and rapidity of onset, the autistic child exhibits a disregard for other persons; this is typically quite striking but in milder cases is more subtle. Little or no eye contact is made, and the child is no more interested in another person than in an article of furniture. Preferred toys are manipulated cleverly, placed in varying lines, or rejected. Insistence on constancy of environment may reach a point where the patient becomes distraught if even a single one of his possessions is moved from its original place and remains distraught until it is replaced. If speech develops at all, it is highly automatic (echolalic) and not used effectively to communicate. A repertoire of elaborate stereotyped movements—such as whirling of the body, manipulating an object, toe walking and particularly hand flapping are characteristic. Spinning toys or running water may have a strange fascination for these children.

It is important to point out, however, that in any sizable group of autistic children *there is a wide range of deficits in sociability, drive, affect, and communicative (verbal and gestural behavior) ability*, ranging from the a verbal negativistic, completely isolated state to one showing considerable language skill and some capacity for attachment to certain people and for scholastic achievement. In this higher-functioning group, taken to typify the Asperger syndrome, the child may be unusually adept in reading, calculating, drawing, or memorizing while still having difficulty in adjusting socially and emotionally to others. Many are clumsy and inept in athletic activities. The least degree of deficit allows success in a professional field but with handicap in the social sphere. We take the current emphasis on the term *autistic spectrum disorders* to reflect a concept that each of the core elements of autism (in social, language, cognitive, and behavioral domains) may occur in widely varying degrees of severity. This view permits a syndromic diagnosis of autism in patients with coexisting elements of other disorders, such as attention deficit disorder and manic-depressive or obsessive-compulsive disorders and expands the diagnosis to many children who are highly functional except for gaze aversion and other “soft signs” ([Filipek](#)).

Rapin, drawing on a large clinical experience with autism, has carefully documented its linguistic, cognitive, and behavioral features. She uses the term *semantic-pragmatic disorder* to designate the characteristic affection of language and behavior and to distinguish it from other forms of developmental disorders and mental retardation.

Elements of autism, but not the whole syndrome with its positive and negative attributes, may appear in other diseases that interfere with brain development, specifically fragile-X and Rett syndromes, and fragmentary similarities are found in a few children with phenylketonuria, tuberous sclerosis, Angelman syndrome, and, rarely, Down syndrome—but these patients are easily distinguished from those with the far more common type of autism. Bolton and Griffiths have made the intriguing observation that autistic traits in patients with tuberous sclerosis correspond to the finding of tubers in the temporal lobe, and DeLong and Heinz point out that patients with seizures from bilateral (but not unilateral) hippocampal sclerosis may fail to develop (or may lose) language ability as well as to acquire social skills after a period of normal development, in a manner similar to idiopathic autism. The IQ of the majority is below 70.

Etiology and Pathology of Autism The basis of childhood autism is as much a mystery today as it was when Kanner and Asperger described it. Most of these children are physically normal except for a larger than average head size, but with no other somatic anomalies. The EEG is normal, as is CT or MRI. The significance of cerebellar vermal changes, reported originally by [Courchesne et al](#), remains to be determined ([Filipek](#)).

In the few brains examined postmortem, no lesions of any of the conventional types were found. In five brains studied in serial sections by [Bauman and Kemper](#), smallness of neurons and increased packing density were observed in the medial temporal areas (hippocampus, subiculum, entorhinal cortex), amygdala and septal nuclei, and mammillary bodies. In a subsequent review of the neuropathology, Kemper and Bauman concluded that three changes stand out: a curtailment of the normal development of neurons in the limbic system; a decrease in the number of Purkinje cells that appears to be congenital; and—in contrast to this—age-related changes in the size and number of the neurons in the diagonal band of Broca (located in the basal frontal septal region) as well as in the cerebellar nuclei and inferior olive. The age-related changes were inferred from studying the brains of autistic children who died at different ages, and they gave the appearance of a progressive or ongoing pathology that continues into adult life. These findings are in keeping with the concept of autism as a neurodevelopmental disorder, but they allow only speculation regarding the derivation of the clinical features of the disease. An increased concentration of platelet serotonin and low serum serotonin is detected in many but not all patients with autism; the biologic significance of these findings is unclear.

Course and Prognosis The disease is essentially nonprogressive, although some patients, as they grow older, begin to manifest additional visuoperceptive or auditory defects. The outcome is bleak, although a group of lesser affected children may show improvement in social relationships and schoolwork with the use of serotonin reuptake inhibitors, sometimes in very small doses ([DeLong](#); [Filipek](#), personal communication). The peptide secretin has produced a number of anecdotal successes, but this outcome could not be reproduced in a controlled study ([Sandler et al](#)). According to Eisenberg, who reviewed many of Kanner's original cases and followed many other cases into adult life, one-third never spoke and remained social isolates, one-third acquired a rudimentary language devoid of communicative value, and the remainder were functional to various degrees with an affected, stilted, colorless speech. It is in the latter group, representing the mildest degrees of autism, that one finds the eccentrics, the mirthless, flat personalities, unable to adapt socially and habitually avoiding eye contact but sometimes possessing certain unusual aptitudes in memory, mathematics, factual knowledge, history, and science. Rutter, who has written extensively on the subject, says that the degree of language impairment and lowered intelligence predicts outcome; those who do not speak by 5 years of age never learn to speak well.

Management of Mental Retardation

Since there is little or no possibility of treating most of the diseases underlying mental retardation and there is no way of restoring function to a nervous system that is developmentally subnormal, the objective is to assist in planning for the patient's care, training, education, and social adjustment. The parents must be guided in forming realistic attitudes and expectations. Psychiatric and social counseling may help the family to maintain gentle but firm support of the patient so that he or she can acquire, to the fullest extent possible, good work habits and a congenial personality.

Most individuals with an IQ above 60 and no other handicaps can be trained to live an independent life: special schooling may enable them to learn skills useful in a vocation. Social factors that contribute to underachievement must be sought and eliminated if possible.

If the IQ is below 20, institutionalization is almost inevitable, for few families can provide the long-term custodial care that is needed. Well-run institutions are usually better than community homes because they offer many more facilities (medical, educational, recreational). Often institutional care is necessary for individuals with IQs of 20 to 50. Patients in this group, if stable in temperament and relatively well adjusted to society, can work under supervision, but they rarely become vocationally independent. For the more severely retarded, special training in hygiene and self-care is the most that can be expected.

Great care must be exercised in recommending institutionalization. Whereas the need will be all too apparent in the gravely retarded by the first or second year of life, the less severely affected are difficult to evaluate at an early age. As stated earlier, psychologic tests alone are not altogether trustworthy. It is best to observe the patient over a period of time. The method of evaluation suggested long ago by Fernald has a ring of soundness, albeit in dated terms. As noted in [Chap. 28](#), the final decision about optimal care is determined by (1) the physical, medical, and neurologic findings; (2) the family background; (3) the developmental history; (4) school progress or lack thereof; (5) performance tests; (6) social behavior; (7) industrial efficiency; (8) what was called in Fernald's time, moral behavior (for example, masturbation); and (9) intelligence as measured by psychological tests.

The adjective *degenerative* has no great appeal to the modern neurologist. For one thing, it has an unpleasant non-medical connotation, referring as it does to a state of moral turpitude or deviant behavior as the consequence of a sociopathic tendency. More important, it is not a satisfactory term medically, since it implies an inexplicable decline from a previous level of normalcy to a lower level of function—an ambiguous conceptualization of disease that satisfies neither theoretician nor scientist.

It is becoming increasingly evident that many of the diseases included in this category depend on genetic factors, or at least they appear in more than one member of the same family, in which case they are more properly designated as *heredodegenerative*. Even more diseases, not differing in any fundamental way from the heredodegenerative ones, occur sporadically, i.e., as isolated instances in given families. For diseases of this type, Gowers in 1902 suggested the term *abiotrophy*, by which he meant a lack of “vital endurance” of the affected neurons, resulting in their premature death. This concept embodies an untested, unproven hypothesis—that aging and degenerative changes of cells are based on the same process. Understandably, contemporary neuropathologists are reluctant to attribute to simple aging the diverse processes of cellular diseases that are constantly being revealed by ultrastructural and molecular genetic techniques.

The reader may be perplexed by the inconsistent use of the terms *atrophy* and *degeneration*, both of which are applied to diseases of this category. Spatz argued that on purely histopathologic grounds they are different. *Atrophy* specifies a gradual wasting and loss of a system of neurons, leaving in their wake no degradative products and only a sparsely cellular, fibrous gliosis. *Degeneration* refers to a more rapid process of neuronal, myelin, or tissue breakdown, the degradative products of which evoke a more vigorous reaction of phagocytosis and cellular gliosis. The difference lies in both the speed and the type of breakdown. It is of some interest that many of the diseases that are characterized by degeneration, in Spatz’s sense of the term, are now known to be of metabolic origin, while very few of the purely atrophic ones have been shown to have a metabolic basis.

The new and fashionable pathologic term for the wasting and dissolution of neurons, in both the system atrophies and the degenerative diseases, is *apoptosis*. This term has been borrowed from embryology, where it refers to the naturally occurring cell death in the central nervous system during development and probably involves the expression of genes that cause a dissolution of neurons over a short period of time (“programmed” cell death), leaving no trace of a pathologic reaction. The process of neuronal degeneration is quite different; it refers to a series of changes in mature neurons, occurring over a relatively protracted period of time and leaving a discrete glial scar.

There are also, within recent memory, several examples of diseases that were formerly classed as degenerative but are now known to have a metabolic, toxic, or nutritional basis or to be caused by a “slow virus” or by a nonviral transmissible agent. It seems reasonable to expect that with increasing knowledge, more and more diseases whose causes are now unknown will find their way into these categories. Until such time as the causation of all neurologic diseases is known, there must be a name and a place for a group of diseases that have no known cause and are united only by the common attribute of gradually progressive disintegration of part or parts of the nervous system. In deference to traditional practice, they are collected here under the rubric *degenerative diseases*.

General Clinical Characteristics

The diseases included in the degenerative category *begin insidiously, after a long period of normal nervous system function, and pursue a gradually progressive course that may continue for many years, often a decade or longer*. In this respect they differ from most of the metabolic diseases. Frequently it is impossible to assign a date of onset. Sometimes, the patient or the patient’s family gives a history of abrupt appearance of disability, particularly if some injury, infection, surgical procedure, or other memorable event coincided with the initial symptoms. Often a skillfully taken history will reveal that the patient or family had been aware of a pre-existent condition, the subtle symptoms of which had been present for some time but had attracted little attention. Whether trauma or other stress can actually evoke or aggravate a degenerative disease is a question that cannot be answered with absolute certainty, but it seems highly improbable. Anyone who states otherwise must offer evidence that at present is purely anecdotal. Instead, these degenerative disease processes by their very nature appear to develop de novo, without relation to known antecedent events, and their symptomatic expressions are late events in the pathologic process, occurring only when the degree of neuronal loss reaches or exceeds the “safety factor” for a particular neuronal system.

The *familial occurrence* of disease is of great importance, but it must be emphasized that such information is often difficult to obtain on first contact with the patient. The family may be small or widely scattered, so that the patient is unaware of the health of other members. The patient or the patient’s relatives may be ashamed to admit that a neurologic disease has “tainted” the family. Furthermore, it may not be realized that an illness is hereditary if other members of the family have a much more or much less severe form of the disorder than the patient. Sometimes, in the latter case, only the careful examination of other family members will disclose the presence of a hereditary disease. It should be remembered, however, that familial occurrence of a disease does not necessarily mean that it is inherited but may indicate instead that more than one member of a family had been exposed to the same infectious or toxic agent.

As a rule, the degenerative diseases of the nervous system run a *ceaselessly progressive course* and with few exceptions are uninfluenced by any medical or surgical measures, so that dealing with a patient with this type of illness may be an anguishing experience for all concerned. However, some of these diseases are

characterized by long periods of stability; moreover, some symptoms (e.g., those of Parkinson disease) can be alleviated by skillful management, and the physician's interest and advice may be of great help.

The bilateral symmetry of the clinical manifestations and lesions is another noteworthy feature of the degenerative diseases; it alone may distinguish members of this group from many other diseases of the nervous system. Again, this principle requires qualification, for in the earliest stages of some degenerative diseases (e.g., Parkinson disease, amyotrophic lateral sclerosis) there may be greater involvement of one limb or one side of the body. Sooner or later, however, despite the asymmetrical beginning, the inherently symmetrical nature of the process asserts itself.

General Pathologic Features

Many of the degenerative diseases are characterized by the *selective involvement of anatomically and physiologically related systems of neurons*. This feature is exemplified by amyotrophic lateral sclerosis, in which the pathologic process is limited to motor neurons of the cerebral cortex, brainstem, and spinal cord, and by certain forms of progressive ataxia, in which only the Purkinje cells of the cerebellum are affected. Many other examples could be cited (e.g., Friedreich ataxia) in which several discrete neuronal systems disintegrate, leaving others unscathed. These degenerative diseases have therefore been called *system atrophies* or *systemic neuronal atrophies*, and many of them turn out to be strongly hereditary. The selective vulnerability of certain systems of neurons is not an exclusive property of the degenerative diseases, however: several disease processes of known cause have similarly circumscribed effects on the nervous system. Diphtheria toxin, for instance, selectively affects the myelin of the peripheral nerves near the spinal ganglia, and triorthocresyl phosphate affects both the corticospinal tracts of the spinal cord and the spinal motor neurons. Other examples are the special vulnerability of the Purkinje cells to hyperthermia, the cerebellar granule cells to methyl mercury compounds, the basal ganglionic neurons to manganese, and the hippocampal neurons to anoxia. Conversely, in Alzheimer disease and most other degenerative diseases, the pathologic changes are somewhat less selective and eventually more diffuse.

As one would expect of any pathologic process that is based on the slow wasting and loss of neurons, not only the cell bodies but also their dendrites, axons, and myelin sheaths disappear—unaccompanied by an intense tissue reaction or cellular response. The cerebrospinal fluid (CSF), therefore, shows little if any change—at most a slight increase in protein content. Moreover, since these diseases invariably result in tissue loss (rather than in new tissue formation, as occurs with neoplasms or inflammations), *radiologic examination shows either no change or a volumetric reduction (atrophy)* with a corresponding enlargement of the CSF compartments. These radiologic findings help distinguish the neuronal atrophies from other large classes of progressive disease of the nervous system—namely, tumors, infections, and other processes of inflammatory type.

CLASSIFICATION

Since grouping of the degenerative diseases in terms of etiology is not possible (except that in many a hereditary, or genetic, factor can be recognized), we resort, for practical purposes, to a division based on the presenting clinical syndromes and their pathologic anatomy. Although this is the most elementary mode of classification of naturally occurring phenomena, it is a necessary prelude to diagnosis and scientific study and preferable to a haphazard listing of diseases by the names of the neurologists or neuropathologists who first described them.

- I. **Syndrome of progressive dementia, other neurologic signs being absent or inconspicuous**
 - A. Diffuse cerebral atrophy
 - 1. Alzheimer disease
 - 2. Diffuse cerebral cortical atrophy of non-Alzheimer type
 - 3. Some cases of Lewy body dementia
 - B. Circumscribed cerebral atrophy
 - 1. Pick disease (lobar sclerosis)
 - 2. Frontotemporal dementia
 - 3. Thalamic degeneration
- II. **Syndrome of progressive dementia in combination with other neurologic abnormalities**
 - A. Huntington chorea
 - B. Other (nonhuntingtonian) types of chorea and dementia
 - C. Cortical-striatal-spinal degeneration ([Jakob](#)) and the dementia–Parkinson–amyotrophic lateral sclerosis complex (Guamanian and others)
 - D. Dentatorubropallidoluysian degeneration (DRPLA)
 - E. Cerebrocerebellar degeneration
 - F. Familial dementia with spastic paraparesis, amyotrophy, or myoclonus
 - G. Lewy body disease
 - H. Some cases of Parkinson disease
 - I. Corticobasal ganglionic degeneration
 - J. Polyglucosan body disease
- III. **Syndrome of disordered posture and movement**
 - A. Parkinson disease (paralysis agitans)
 - B. Striatonigral degeneration with or without autonomic failure (Shy-Drager syndrome) and olivopontocerebellar atrophy (multiple system atrophy)
 - C. Progressive supranuclear palsy (Steele-Richardson-Olszewski)
 - D. Dystonia musculorum deformans (torsion spasm)
 - E. Hallervorden-Spatz disease
 - F. Corticobasal ganglionic degeneration
 - G. Restricted dystonias, including spasmodic torticollis and Meige syndrome
 - H. Familial tremors
 - I. Multiple tic disease (Gilles de la Tourette syndrome)
 - J. Acanthocytic chorea
- IV. **Syndrome of progressive ataxia**
 - A. Spinocerebellar ataxias (early onset)
 - 1. Friedreich ataxia
 - 2. Non-Friedreich, early-onset ataxia (with retained reflexes, hypogonadism, myoclonus, and other disorders)
 - B. Cerebellar cortical ataxias
 - 1. Holmes type of familial pure cerebellar-olivary atrophy
 - 2. Late-onset cerebellar atrophy of Marie, Foix, and Alajouanine
 - C. Complicated cerebellar ataxia (later-onset ataxia with brainstem and other neurologic disorders)
 - 1. Olivopontocerebellar degenerations (OPCA)
 - a. Clinically pure (Déjerine-Thomas type)
 - b. With extrapyramidal and autonomic degeneration (multiple system atrophy)
 - c. Conjoined with spinocerebellar degeneration (Menzel type)
 - 2. Dentatorubral degeneration (Ramsay Hunt type)
 - 3. Dentatorubropallidoluysian atrophy
 - 4. Machado-Joseph-Azorean disease
 - 5. Other complicated late-onset, autosomal dominant ataxias (including Harding's types 1, 2, and 3) with pigmentary retinopathy, ophthalmoplegia, slow eye movements ([Wadia](#)), neuropathy, optic atrophy, deafness, extrapyramidal features, and dementia
- V. **Syndrome of slowly developing muscular weakness and atrophy (nuclear amyotrophy)**
 - A. *Motor disorders with amyotrophy: motor system disease*
 - 1. Amyotrophic lateral sclerosis
 - 2. Progressive spinal muscular atrophy
 - 3. Progressive bulbar palsy
 - 4. Hereditary forms of progressive muscular atrophy and spastic paraplegia
 - B. *Spastic paraplegia without amyotrophy*
 - 1. Primary lateral sclerosis
 - 2. Hereditary spastic paraplegia

VI. **Sensory and sensorimotor disorders (neuropathies)**

- A. Hereditary sensorimotor neuropathies—peroneal muscular atrophy (Charcot-Marie-Tooth); hypertrophic interstitial polyneuropathy ([Déjerine-Sottas](#)); Refsum disease; etc.

VII. **Syndrome of progressive blindness or ophthalmoplegia with or without other neurologic disorders**

- A. Hereditary optic neuropathy (Leber)
B. Pigmentary degeneration of retina (retinitis pigmentosa)
C. Stargardt disease
D. Progressive external ophthalmoplegia with or without deafness or other system atrophies (Kearns-Sayre syndrome)

VIII. **Syndromes characterized by neurosensory deafness**

- A. Pure neurosensory deafness
B. Hereditary hearing loss with retinal diseases
C. Hereditary hearing loss with system atrophies of the nervous system

DISEASES CHARACTERIZED MAINLY BY PROGRESSIVE DEMENTIA

Alzheimer Disease

This is the most common and important degenerative disease of the brain, incurring to an increasing degree an immense societal impact. Some aspects of the intellectual deterioration that characterizes this disease have already been described in [Chap. 21](#), under “The Neurology of Dementia,” and the relationship of this disease to the aging process has been fully discussed in [Chap. 29](#). There it was pointed out that some degree of shrinkage in size and weight of the brain, i.e., “atrophy,” is an inevitable accompaniment of advancing age, but that these changes alone are of slight clinical significance and their structural basis is uncertain (e.g., slight loss of brain weight or simple depletion of neurons). By contrast, severe degrees of diffuse cerebral atrophy that evolve over a few years are invariably associated with dementia, and the underlying pathologic changes in these cases most often prove to be those of Alzheimer disease. For this reason it is usual to speak of the clinical syndrome as *dementia of the Alzheimer type* (DAT) or *probable Alzheimer disease*, if the diagnosis is uncertain. The traditional practice of giving Alzheimer disease and senile dementia the status of separate diseases was probably attributable to the relatively young age (51 years) of the patient originally studied by Alois Alzheimer in 1907. Such a division is illogical, since the two conditions, except for their age of onset, are clinically and pathologically indistinguishable. There is a smooth, exponential, age-dependent increase in incidence after 40 years of age.

Epidemiology Although Alzheimer disease has been described at every period of adult life, the majority of patients are in their sixties or older; a relatively small number have been in their late fifties or younger. It is one of the most frequent mental illnesses, making up some 20 percent of all patients in psychiatric hospitals and an even larger proportion in nursing homes. In the United States, in 17 series comprising 15,000 persons over the age of 60 years, the mean incidence of moderate to severe dementia was calculated to be 4.8 percent ([Wang](#)). In Rochester, Minnesota, the incidence rate for dementia in general is 187 cases per 100,000 population per year, and for Alzheimer disease, 123 cases per 100,000 annually ([Schoenberg et al](#)).

These staggering statistics may be viewed from another perspective. The incidence rate of clinically diagnosed Alzheimer disease is similar throughout the world, and it increases comparably with age, approximating 3 new cases yearly per 100,000 persons below age 60 and 125 new cases per 100,000 of those over 60. The prevalence of the disease per 100,000 population is near 300 in the group aged 60 to 69; it is 3200 in the 70-to-79 group and 10,800 in those over age 80. In the year 2000, there were an estimated 2 million persons with Alzheimer disease in the United States. Prevalence rates, which depend also on overall mortality, are three times higher in women, although it does appear that the incidence of new cases is only slightly disproportionate in women. The survival of patients with Alzheimer disease is reduced to half of the expected rate, most of the deaths occurring ultimately from respiratory and cardiovascular causes.

Several putative epidemiologic risk factors for Alzheimer disease—such as birth order, mother's age at birth, family history of Down syndrome, or head injury—seem marginal at best and in some instances may be due to selection bias. Whether low educational attainment is a risk factor for the development of Alzheimer disease or, conversely, whether cognitively demanding occupations protect against dementia has not been settled ([Katzman](#); [Cobb et al](#)).

The *familial occurrence* of Alzheimer disease, accounting for less than 1 percent of all cases, has been well established, most of the pedigrees being consistent with an autosomal dominant inheritance ([Nee et al](#), [Goudsmit et al](#); see further on, in the section on pathogenesis). Reports of a substantial familial aggregation of dementia without a specific pattern of inheritance also suggest the operation of more than one genetic factor. Several studies have documented a significant increase in the risk of apparently sporadic Alzheimer disease among first-degree relatives of patients with this disorder. Again, this risk is disproportionately greater in females, adding to the evidence that women in general are at slightly higher risk for Alzheimer disease ([Silverman et al](#)). Li and coworkers have provided evidence that patients with an earlier age of onset of Alzheimer disease (before age 70) are more likely to have relatives with the disease than are patients with later onset. Genetic studies are difficult because the disease does not appear at the same age in a given proband. Even in identical twins, it may develop at the age of 60 years in one of the pair and at 80 years in the other. Death from other diseases may prevent its detection.

Clinical Features The onset of mental changes is usually so insidious that neither the family nor the patient can date the time of its beginning. Occasionally, however, it is brought to attention by an unusual degree of confusion in relation to a febrile illness, an operation, mild head injury, or the taking of medication. Other patients may present with complaints of dizziness, nondescript headaches, or other vaguely expressed and changeable somatic symptoms.

The gradual development of forgetfulness is the major symptom. Small day-to-day happenings are not remembered. Seldom-used names are particularly elusive. Little-used words from an earlier period of life also tend to be lost. Appointments are forgotten and possessions misplaced. Questions are repeated again and again, the patient having forgotten what was just discussed. It is said that remote memories are preserved and recent ones lost (Ribot's law of memory), but this is only relatively true; it is difficult to check the accuracy of ancient memories. Albert and associates, who tested the patient's recognition of dated political events and pictures of prominent people past and present, found that some degree of memory loss extends to all decades of life (specific neuropsychological testing is discussed further on).

Once the memory disorder has become pronounced, other failures in cerebral function become increasingly apparent. The patient's speech is halting because of failure to recall the needed word. The same difficulty interrupts writing. Vocabulary becomes restricted, and expressive language stereotyped and inflexible. Comprehension of spoken words seems at first to be preserved, until it is observed that the patient does not carry out a complicated request; even then it is uncertain whether the request was not understood because of inattention or was forgotten. Almost imperceptible at first, these disturbances of language become more apparent as the disease progresses. Finally, there is a failure to speak in full sentences; the finding of words requires a continuous search; and little that is said or written is fully comprehended. There is a tendency to repeat a question before answering it, and later there may be a rather dramatic repetition of every spoken phrase (*echolalia*). The deterioration of verbal skills has by then progressed beyond a groping for names and common nouns to an obvious anomic aphasia. Other elements of receptive and executive aphasia are later added, but discrete aphasias of the Broca or Wernicke type are characteristically lacking.

Skill in arithmetic suffers a similar deterioration. Faults in balancing the checkbook, mistakes in figuring the price of items and in making the correct change—all these and others progress to a point where the patient can no longer carry out the simplest calculations (*acalculia* or *dyscalculia*).

In some patients, visuospatial orientation becomes defective. The car cannot be parked; the arms do not find the correct sleeves of the dressing gown; the corners of the tablecloth cannot be oriented with the corners of the table; the patient turns in the wrong direction on the way home or becomes lost. The route from one place to another cannot be described, nor can given directions be understood. As this state worsens, the simplest of geometric forms and patterns cannot be copied.

Late in the course of the illness, the patient forgets how to use common objects and tools while retaining the necessary motor power and co-ordination for these activities. The razor is no longer correctly applied to the face; the latch of the door cannot be unfastened; and eating utensils are no longer used properly. Finally, only the most habitual and virtually automatic actions are preserved. Tests of commanded and demonstrated actions cannot be executed or imitated. *Ideational* and *ideomotor apraxia* are the terms applied to the advanced forms of this motor incapacity (pages 59 and 486).

As these many amnesic, aphasic, agnosic, and apraxic deficits declare themselves, the patient at first seems unchanged in overall motility, behavior, temperament, and conduct. Social graces, whatever they were, are retained in the initial phase of the illness, but troublesome alterations gradually appear in this sphere as well. Imprudent business deals may be made. Restlessness and agitation or their opposites—inertia and placidity—become evident. Dressing, shaving, and bathing are neglected. Anxieties and phobias, particularly fear of being left alone, may emerge. A disturbance of the normal day and night sleep patterns is prominent in some patients. A poorly organized paranoid delusional state, sometimes with hallucinations, may become manifest. The patient may suspect his elderly wife of having an

illicit relationship or his children of stealing his possessions. A stable marriage may be disrupted by the patient's infatuation with a younger person or by sexual indiscretions, which may astonish the community. The patient's affect coarsens; he is more egocentric and indifferent to the feelings and reactions of others. A gluttonous appetite sometimes develops, but more often eating is neglected, with gradual weight loss. Later, grasping and sucking reflexes and other signs of frontal lobe disorder are readily elicited ([Neary et al](#)), sphincteric continence fails, and the patient sinks into a state of relative akinesia and mutism, as described in [Chap. 21](#).

Difficulty in locomotion, a kind of unsteadiness with shortened steps but with only slight motor weakness and rigidity, frequently supervenes. Elements of parkinsonian akinesia and rigidity and a fine tremor can be perceived in patients with advanced motor disability. Ultimately the patient loses the ability to stand and walk, being forced to lie inert in bed and having to be fed and bathed, and the legs may curl into a fixed posture of paraplegia in flexion (persistent vegetative state; page 369).

The symptomatic course of this tragic illness usually extends over a period of 5 or more years but, judging from studies of Down cases, the pathologic course has a much longer asymptomatic duration. This concept is supported by the detailed studies of Linn and colleagues, who found that a lengthy "preclinical" period (7 years or more) of stepwise decline in memory and attention span preceded the clinical diagnosis. Surprisingly, throughout this period, corticospinal and cortic sensory functions, visual acuity, ocular movements, and visual fields remain relatively intact. If there is hemiplegia, homonymous hemianopia, etc., either the diagnosis of Alzheimer disease is incorrect or the disease has been complicated by a stroke, tumor, or subdural hematoma. Exceptions to this statement are rare. The tendon reflexes are little altered and the plantar reflexes almost always remain flexor. There is no true sensory or cerebellar ataxia. Convulsions are rare until late in the illness, when up to 5 percent of patients reportedly have infrequent seizures. Occasionally, widespread myoclonic jerks or mild choreoathetotic movements are observed late in the illness. Eventually, with the patient in a bedfast state, an intercurrent infection such as aspiration pneumonia or some other disease mercifully terminates life.

The sequence of neurologic disabilities may not follow this described order, and one or another deficit may take precedence, presumably because the disease process, after becoming manifest in the memory cortex of the temporal lobes, may affect one particular part of the associative cortex earlier or more severely in one patient than in another. This allows a relatively restricted deficit to become the source of early medical complaint long before the full syndrome of dementia has declared itself. We have observed four limited deficits of this type, as follows:

1. *Korsakoff amnesic state*. The early stages of Alzheimer disease may be dominated by a disproportionate failure of retentive memory, with integrity of other cognitive abilities. In such patients, immediate memory (essentially a measure of attention), tested by the capacity to repeat a series of numbers or words, is essentially intact; it is the short- and long-term (retentive) memory that fails. Retentive memory may become impaired to the point where the patient can recall nothing of what he had learned a minute or two previously. Yet as a business executive, for example, he may continue to make acceptable decisions if the work utilizes long-established habit patterns and practices. In such cases, the temporal horns tend to be enlarged more than the rest of the ventricular system, reflecting the disproportionate atrophy of the inferomedial temporal lobes.
2. *Dysnomia*. The forgetting of words, especially proper names, may first bring the patient to a neurologist. Later the difficulty involves common nouns and progresses to the point where fluency of speech is seriously impaired. Every sentence is broken by a pause and search for the wanted word; if this is not found, a circumlocution is substituted or the sentence is left unfinished. When the patient is given a choice of words, including the one that was missed, there may be a failure of recognition. Repetition of the spoken words of others, at first flawless, later brings out a lesser degree of the same difficulty. A useful test for the failure to find names (*dysnomia*), which is probably the most common abnormality of language in this disease, is the category-fluency test. The patient is given 1 min to name as many items as possible in each of four categories—vegetables, vehicles, tools, and clothing. Alzheimer patients fall below a score of 50 items. The naming defect may be evident with even simpler tests, e.g., asking the patient to generate a list of farm animals—a test that may elicit only three or four responses. Other components of language may be relatively intact, but before long it is evident that the patient does not understand all that he hears or reads. In contrast, nonverbal memory and the ability to calculate and make simple judgments may still be preserved. Duplicating our own experience, Mesulam and Chawluk and their colleagues have described patients in whom an aphasic disorder began with anomia and eventually affected reading, writing, and comprehension without the additional intellectual and behavioral disturbances of dementia. In our own observation of such patients, if observed for a sufficiently long period, develop a more general dementia, sometimes as long as 5 years or more after the onset of aphasia. Rarely, this syndrome represents a focal degenerative disorder (lobar atrophy of Pick or frontotemporal dementia), distinct from Alzheimer disease ([Lippa et al](#), [Kirshner et al](#)). Usually the electroencephalogram (EEG) is normal or shows only a mild degree of slowing, but magnetic resonance imaging (MRI) may disclose a focal atrophy of the language areas ([Caselli et al](#)).
3. *Visuospatial disorientation*. Parieto-occipital functions are sometimes deranged in the course of Alzheimer disease and may fail while other functions are relatively preserved. As remarked above and in [Chap. 22](#), prosopagnosia, losing one's way in familiar surroundings or inability to interpret a road map, to distinguish right from left, or to park or garage a car, and difficulty in setting the table or dressing are all manifestations of a special failure to orient the schema of one's body with that of surrounding space. Exceptionally there is a neglect of stimuli in one visual field.
4. *Paranoia and other personality changes*. Frequently, at some point in the development of senile dementia, the most prominent event is the occurrence of paranoia or bizarre behavior. The patient becomes convinced that relatives are stealing his possessions or that an elderly and even infirm spouse is guilty of infidelity. He may hide his belongings, even relatively worthless ones, and go about spying on family members. Hostilities arise, and wills may be altered irrationally. Many of these patients are constantly worried, tense, and agitated. Of course, paranoid delusions may be part of a depressive psychosis and of other dementias, but most of the senile patients in whom paranoia is the presenting problem seem not to be depressed, and their cognitive functions are for a time relatively well preserved. It is tempting to think that a very early senile change of the limbic cortices has exposed a lifelong trait of suspiciousness, but this is purely hypothetical.

Sometimes other oddities of behavior will announce the oncoming dementia. Social indiscretions, rejection of an old friend, embarking on an imprudent financial venture, or an amorous pursuit that is out of character are examples of these types of behavioral change.

Some clinicians attempt to subdivide the Alzheimer–senile dementia syndrome into subtypes. Amnesic defect without lexical-semantic abnormalities represents more than 50 percent of cases. Chin and coworkers observed more prevalent and severe language disorder and more rapid progression in early-onset familial cases. Others point to a disproportionately severe defect in praxic functions and a greater tendency to abnormal EEG findings in such cases. Whether such distinctions represent fundamental differences in the disease process is questionable.

It has been our impression that each of the restricted cerebral disorders described above is only *relatively pure*. Careful testing of mental function—and this is of diagnostic importance—frequently discloses subtle abnormalities in several cognitive spheres. Initially, most patients have a disproportionate affection of the temporoparietal cortices, hence the earlier impairment on the performance parts of the Wechsler Adult Intelligence Scale. Within several months to a year or two, the more generalized aspects of mental deterioration become apparent, and the aphasic-agnosic-apraxic aspects of the syndrome become increasingly prominent. If one of the foregoing restricted deficits remains uncomplicated over a period of years, one is justified in suspecting some cause other than Alzheimer disease, such as Binswanger disease, hydrocephalus, frontotemporal dementia (see further on), or embolic infarction of one part of the temporal or parietal lobe (pages 451 and 878). Also, as stated earlier, a hemianopic visual field defect, cortical sensory loss, or hemiparesis is seldom if ever due to Alzheimer disease alone. However, more complex disturbances of visual perception, taking the form of impaired recognition of objects (*object agnosia*) or faces (*prosopagnosia*), visual scanning, color identification, stereoacuity, separation of figures from background, and hand-eye coordination, are frequent in the more advanced stages ([Mendez et al](#)). Rarely there is a partial or even a complete Balint syndrome (page 491).

While it is true that most patients with Alzheimer disease walk normally until relatively late in their illness, infrequently a short-stepped gait and imbalance draw attention to the disease and worsen slowly for several years before cognitive manifestations become evident.

For research purposes and to establish certain inclusive and exclusive criteria for the diagnosis of Alzheimer disease, a work group of the National Institute of Neurological and Communicative Disorders and Stroke (NINCDS) and the Alzheimer's Disease and Related Diseases Association (ADRDA) have proposed the following diagnostic criteria: (1) dementia defined by clinical examination, the Mini-Mental Scale, the Blessed Dementia Scale, or similar mental status examination; (2) age of patient (over 40 years); (3) deficits in two or more areas of cognition and progressive worsening of memory and other cognitive functions—such as language, perception, and motor skills (praxis); (4) absence of disturbed consciousness; and (5) exclusion of other brain diseases ([McKhann et al](#); [Tierney et al](#)). Using these criteria, the correct diagnosis is achieved in more than 85 percent of patients.

Pathology In the advanced stages of the disease, the brain presents a diffusely atrophied appearance and brain weight is usually reduced by 20 percent or more ([Fig. 39-1](#)). Cerebral convolutions are narrowed and sulci are widened. The third and lateral ventricles are symmetrically enlarged to a varying degree. Usually the atrophic process involves the frontal, temporal, and parietal lobes, but cases vary considerably. The extreme atrophy of the hippocampus—the most prominent finding, visible on coronal MRI—is believed to be diagnostic. Microscopically, there is widespread loss of nerve cells, most marked in the cerebral cortex. In addition to pronounced neuronal loss in the hippocampus, adjacent parts of the medial temporal cortex—namely, the entorhinal cortex, parahippocampal gyri, and subiculum—are affected. The anterior nuclei of the thalamus, septal nuclei and diagonal band of Broca, the amygdala, and particular brainstem parts of the

monoaminergic systems are also depleted. The cholinergic neurons of the nucleus basalis of Meynert (the substantia innominata) and locus ceruleus are also reduced in number, a finding that at one time aroused great interest because of its putative role in memory loss (see below). In the cerebral cortex, the cell loss affects both large pyramidal neurons and smaller interneurons. Residual neurons are observed to have lost volume and ribonucleoprotein and their dendrites are diminished and crowd upon one another owing to the loss of synapses and neuropil. Astrocytic proliferation follows as a compensatory or reparative process, most prominent in layers III and V.

Figure 39-1 *Top: Alzheimer disease. Axial CT section demonstrating severe generalized cerebral cortical atrophy and moderately severe ventricular enlargement. Bottom: Pick disease. Pronounced selective atrophy of the frontal and temporal lobes. (From Lee SH, Rao KCVG, Zimmerman RA: Cranial MRI and CT. New York, McGraw-Hill, 1992, by permission.)*

In addition, three microscopic changes give this disease its distinctive character: (1) the presence within the nerve cell cytoplasm of thick, fiber-like strands of silver-staining material, often in the form of loops, coils, or tangled masses (Alzheimer neurofibrillary change, or “tangles”). The strands are composed of a hyperphosphorylated form of the microtubular protein “tau” and appear as pairs of helical filaments when studied ultrastructurally; (2) spherical deposits of amorphous material scattered throughout the cerebral cortex and most easily seen with periodic acid–Schiff (PAS) and silver-staining methods; the core of the aggregates is the protein amyloid, surrounded by degenerating nerve terminals (*senile* or *neuritic plaques*). Amyloid is also scattered throughout the cerebral cortex in a nascent “diffuse” form, without organization or core formation and appreciated mainly by immunohistochemical methods, as well as in the walls of small blood vessels near the plaques— so-called congophilic angiopathy; (3) *granulovacuolar degeneration* of neurons, most evident in the pyramidal layer of the hippocampus.

Neuritic plaques and neurofibrillary changes are found in all the association areas of the cerebral cortex, but it is the neurofibrillary tangles and neuronal alterations and loss, not the plaques, that correlate best with the severity of the dementia ([Arriagada et al](#)). If any part of the brain is disproportionately affected, it is the hippocampus, particularly the CA1 and CA2 zones (of Lorente de Nó) and the entorhinal cortex, subiculum, and amygdala. These parts have abundant connections with other parts of the temporal lobe cortex and dentate nucleus of the hippocampus and undoubtedly account for the amnesic component of the dementia. The parietal lobes are another favored site. Only a few tangles and plaques are found in the hypothalamus, thalamus, periaqueductal region, pontine tegmentum, and granule-cell layer of the cerebellum.

Experienced neuropathologists recognize a form of Alzheimer disease, particularly in older patients (>75 years), in which there are senile plaques but few or no neuronal tangles (20 percent of 150 cases reported by Joachim et al). [In general, senile (neuritic) plaques are found to be more diffusely distributed than the fibrillary changes.] Another problem for the neuropathologist is to distinguish between the normal aged brain and that of Alzheimer disease. It is not unusual to find a scattering of senile plaques in individuals who were thought to be mentally normal during life. Henderson and Hubbard studied 27 demented individuals aged 64 to 92 years and 20 age-matched, nondemented controls. In the former, 3 to 38 percent of the hippocampal neurons contained neurofibrillary tangles; in all but 2 of the controls, the number of hippocampal neurons with tangles fell below 2.5 percent. Hence, the difference between plaques and tangles in the aging brain and in Alzheimer disease is largely quantitative.

Of interest also is the observation of Joachim and associates that 18 percent of their Alzheimer cases had sufficient neuronal loss and Lewy bodies in the substantia nigra to justify a diagnosis of Parkinson disease. Leverenz and Sumi found that 25 percent of their Alzheimer patients showed the pathologic (and clinical) changes of Parkinson disease—a much higher incidence than can be attributed to chance. Also, of 11 patients with progressive supranuclear palsy reported by Gearing and coworkers, 10 were demented and 5 had Alzheimer disease. These mixed cases, including those with Pick disease, present problems not only of classification, but also in understanding the neurobiology of these degenerative diseases. This subject is discussed further on in the section on Parkinson disease.

It is of historical interest that Alzheimer was not the first to describe plaques, one of the hallmarks of this pathologic state. These miliary lesions (“*Herdchen*”) had been observed in senile brains by Blocq and Marinesco in 1892 and were named *senile plaques* by Simchowicz in 1910. In 1907, Alzheimer described the case of a 51-year-old woman who died after a 5-year illness characterized by progressive dementia. Throughout the cerebral cortex he found the characteristic plaques, but he also noted—thanks to the use of Bielschowsky’s silver impregnation method—a clumping and distortion of fibrils in the neuronal cytoplasm, the neurofibrillary change which now, appropriately, carries Alzheimer’s name.

Pathogenesis Careful analyses of the senile plaques and neuronal fibrillary changes have been made in recent years in an attempt to elucidate the mechanism of Alzheimer disease. Several new histologic techniques have been devised and put to service in this endeavor—refinements of the silver impregnation method, which stains both amyloid and its main constituent (amyloid b protein, or Ab); immunoreactive methods, using antibodies raised to rabbit thymus (ubiquitin), to demonstrate neuronal tau protein and amyloid b protein; and thioflavine S and Congo red with ultraviolet and polarized light to identify amyloid b protein and amyloid. Tau is a discrete cytoskeletal protein that is thought to promote the assembly of microtubules and to stabilize their structure as well as to participate in synaptic plasticity in a yet to be defined manner. In the pathologic circumstances of Alzheimer disease, progressive supranuclear palsy, and frontotemporal dementia (see further on), tau is hyperphosphorylated and aggregates, resulting in an overloading of the perikarya and neurites with paired helical filaments which constitute neurofibrillary tangles. Electrophoretically, tau moves with the beta₂ globulins and is thought to function as a transferrin, i.e., it binds iron and delivers it to the cell. Tau can be measured in the CSF and serum.

The Ab protein is a small portion of a set of amino acids collectively referred to as the *amyloid b-protein precursor* (APP), which is normally bound to neuronal membranes. The Ab protein is cleaved from the APP by the action of proteases termed a, b, and d secretase. A current hypothesis, favored by Selkoe, focuses on the manner in which APP is cleaved by these enzymes to give rise to different-length residues of Ab, normally secreted as a 40–amino acid product, Ab₄₀, and as a longer 42–amino acid form, Ab₄₂. The latter assumes a nonfibrillar amorphous form, the main ingredient in the diffuse plaque, and in theory is believed to be toxic to neurons. It may be the d form of secretase that is largely responsible for creating the longer Ab₄₂ fragment. This might offer a potential method of treatment by blocking the activity this enzyme.

Several pieces of evidence favor this hypothesis. It appears that the diffuse deposition of Ab₄₂ precedes the formation of neurofibrils and plaques. The fact that the gene coding for APP is located on chromosome 21, one of the regions linked to familial Alzheimer disease, and that this chromosome is the one duplicated in the Down syndrome (see further on), suggests a causative connection between the overproduction of amyloid and all its Ab residues and the disease. Another suggestive connection between these mechanisms has been the finding that the gene errors in several forms of familial Alzheimer disease code for a category of endosomal proteins termed *presenilins*, which interact with, or may indeed be, the d secretase enzyme that produces Ab₄₂. Transgenic mice with mutations for APP or for human presenilins develop plaques with Ab₄₂ but not neurofibrillary tangles. Also, there is a provocative relationship between certain circulating proteins, particularly lipoproteins, and amyloid; this is discussed further on. It should be noted in this regard that mutations of the APP gene, detailed below, are associated with fewer than 0.1 percent of Alzheimer patients ([Terry](#)).

It must be conceded that there is still considerable uncertainty about the relationship of these changes to the loss of nerve cells and brain atrophy. The finding of a reduced number and enlargement of synapses in affected cortex by DeKosky and Scheff and others could be interpreted as either the first sign of neuronal death or the result of the neuronal loss. Amyloid deposition would then be a secondary phenomenon. The primary role of neurofibrillary tangles has also been questioned, and the manner in which amyloid deposition relates to tangle formation is unclear. Unexplained also is the prominent senile plaque formation in some cases and neurofibrillary tangles in others. Nonetheless, the amyloid hypothesis is currently the strongest, and all the more interesting insofar as APP and its Ab products seem

to have no useful purpose in the organism and conceivably could be reduced in quantity without harm.

Vascular changes do not have an important role in the pathogenesis of Alzheimer disease. It is definite that Alzheimer disease is not related to any of the usual types of arteriosclerosis. There are, however, small-vessel changes, accounting for the reduced cerebral blood flow reported by many investigators. This small-vessel change is probably secondary to the cerebral atrophy, since a lesser degree of reduction in cerebral blood flow is found in mentally intact old individuals. Probably the deposition of amyloid in cerebral vessels is a secondary phenomenon as well. The initial reports of the transmissibility of Alzheimer disease ([Goudsmit et al](#)) have not been corroborated.

No relationship to premorbid personality traits or to the level of cognitive functioning earlier in life has been established, but an intriguing finding from what has become known as the “nun study” suggests that poor linguistic ability early in life corresponds to the later development of Alzheimer disease ([DA Snowden et al](#)). In this study, the autobiographies of 93 nuns, written in their twenties, were rated for linguistic and ideational complexity. Of 14 sisters who died in late life, deterioration of cognitive function and neuropathologically proven Alzheimer disease occurred in 7 who had low “idea density” in their writings and in none of 7 whose writings were cognitively more complex. Obviously this correlation requires further study.

Neurotransmitter Abnormalities Considerable interest was created in the late 1970s by the finding of a marked reduction in choline acetyltransferase (ChAT) and acetylcholine in the hippocampus and neocortex of patients with Alzheimer disease. This loss of cholinergic synthetic capacity was attributed to the loss of cells in the basal forebrain nuclei (nucleus basalis of Meynert), from which the major portion of neocortical cholinergic terminals originate ([Whitehouse et al](#)). As is often true in medical science, the early enthusiasm for the cholinergic hypothesis proved less justified in the light of subsequent research. A 50 percent reduction in ChAT activity has been found in regions such as the caudate nucleus, which show neither plaques nor tangles (see review of [Selkoe](#)). The specificity of the nucleus basalis-cholinergic-cortical changes was questioned for other reasons as well. Also, the Alzheimer brain shows a loss of monoaminergic neurons in addition to cholinergic ones and a diminution of noradrenergic, GABAergic, and serotonergic functions in the affected neocortex. The concentration of amino acid transmitters, particularly of glutamate, is also reduced in cortical and subcortical areas ([Sasaki et al](#)). The Alzheimer cortex shows a decreased concentration of several neuropeptide transmitters—notably substance P, somatostatin, and cholecystokinin—but it has not been determined whether any of the aforementioned biochemical abnormalities, including the cholinergic ones, are primary or are secondary to heterogeneous neuronal loss. Finally, the administration of cholinomimetics—whether they be acetylcholine precursors (e.g., choline or lecithin), degradation inhibitors (e.g., physostigmine), or muscarinic agonists that act directly on postsynaptic receptors—has not had a sustained therapeutic effect.

Chase and associates have demonstrated a 30 percent reduction in cerebral glucose metabolism in Alzheimer disease, greatest in the parietal lobes, but again the meaning of this, whether it is due to loss or to hypofunction of neurons, remains to be decided. The significance of aluminum in the genesis of neurofibrillary tangles, as once proposed, has never been determined. Recently it has been suggested that the use of estrogen by postmenopausal women delays the onset of the disease and might reduce its frequency ([Tang et al](#)). Carefully constructed, prospective studies are needed to test this idea and the long-term safety of the drug.

Genetic Aspects of Alzheimer Disease Of great interest and potential importance was the discovery, in patients with the clearly inherited form of Alzheimer disease, of a defective gene localized to a region of chromosome 21, near the b-amyloid gene that codes for an errant amyloid precursor protein (APP) ([St. George-Hyslop et al](#)). This also provided a possible explanation for the Alzheimer changes that characterize practically all patients with the trisomy 21 defect (Down syndrome) after their 20th year, but the gene defect on chromosome 21, as already noted, is responsible for only a tiny percentage of proved familial cases. Other kindreds with familial Alzheimer disease have been linked to gene mutations of chromosome 14 ([Sherrington et al](#)), accounting for up to 50 percent of familial cases, and on chromosome 1, which may account for many of the remaining inherited cases ([Levy-Lahad et al](#)). These genes and their protein products are now termed presenilin-1 and presenilin-2, respectively, to distinguish them from the APP mutations on chromosome 21; numerous mutations at these sites have been determined. The age of onset of the disease in these familial forms, as in the Down cases, is earlier than that in sporadic forms; asynchronous myoclonus, epilepsy, aphasia, and paratonia are more prominent in the familial disease.

Apolipoprotein E, a regulator of lipid metabolism that has an affinity for the b-amyloid protein in Alzheimer plaques, has been found to be another genetic marker that greatly modifies the risk of acquiring Alzheimer disease. Of the several isoforms of apolipoprotein E, the presence of E4 (and its corresponding gene allele e4 on chromosome 19) is associated with a tripling of the risk of developing sporadic Alzheimer disease ([Roses, Strittmatter et al](#), and [Polvikoski et al](#)). (This is the same allele that contributes to an elevated low-density lipoprotein fraction in the serum.) Possession of two e4 alleles virtually assures the development of disease in those who survive to their eighties. The e4 allele also modifies the age of onset of some of the familial forms of the disease. In contrast, the e2 allele is underrepresented among Alzheimer patients. For these reasons it has been proposed that apolipoprotein E, by interacting with APP or tau protein in some way, modifies the formation of plaques.

These findings have led to interest in using the e4 genotype as a marker for the risk of Alzheimer disease, but it must be pointed out that these are statistical relationships that do not invariably connect the allele to the disease in a particular individual. Therefore the results of such testing must be interpreted with caution. The e4 allele does not act as a mendelian trait but as a susceptibility (risk) factor. It follows that many individuals without the allele also develop Alzheimer disease.

Studies of the molecular genetics of Alzheimer disease are yielding new information at such an astonishing rate that much of the foregoing text will soon be outdated. Useful basic reviews of this subject are those of Martin and of Selkoe, listed in the references.

Diagnostic Studies The most important ancillary tests in routine use are CT scanning and MRI ([Fig. 39-1](#)). In patients with advanced Alzheimer disease, the lateral and third ventricles are enlarged to about twice normal size and the cerebral sulci are widened. As stated previously, fine-section coronal MRI of the medial temporal lobes reveals a disproportionate atrophy of the hippocampi and a corresponding enlargement of the temporal horns of the lateral ventricles. Early in the disease, however, the changes do not exceed those found in many mentally intact old persons. For this reason, one cannot rely on imaging procedures alone for diagnosis. They are most valuable in excluding brain tumor, subdural hematoma, multi-infarct dementia, and obstructive hydrocephalus. The EEG undergoes a diffuse slowing, to the theta and delta range, but only late in the course of the illness. The CSF is also normal, though occasionally the total protein is slightly elevated. Using the constellation of clinical data, CT scanning, and MRI—along with the age of the patient and time course of the disease—the diagnosis of senile dementia of Alzheimer type is being made correctly in 85 to 90 percent of cases.

Neuropsychologic tests show a deterioration in memory and verbal access skills. Testing is particularly useful when there is a serial decline in ability. The use of these examinations is described in [Chap. 21](#). Certain aspects of attention and executive function in Alzheimer disease have recently been reviewed by Perry and Hodges.

There is no available biologic marker of Alzheimer disease with the exception of an imprecise association with the disease-modifying e4 apolipoprotein allele, as mentioned earlier. The specificity of certain pupillary reactions has been negated. Interest in this subject followed a report that Alzheimer patients show an enhanced pupillary sensitivity (mydriasis) to instillation of tropicamide eyedrops. Subsequent studies have failed to replicate these observations. The measurement of amyloid protein and its derivatives in the spinal fluid and blood are being investigated as diagnostic tests.

Differential Diagnosis Formerly, when virtually all forms of presenile and senile dementia were untreatable, there was little advantage to either the patient or the family in ascertaining the cause of the cerebral disease. Such patients were customarily left at home or committed to an institution for care of the psychiatrically or chronically ill. Now that a number of dementing diseases are treatable, a great premium attaches to correct diagnosis. The physician is compelled to exercise care in their detection even though they may be relatively infrequent.

The treatable forms of dementia are those due to neurosyphilis (general paresis) and other chronic meningitides, normal-pressure hydrocephalus, chronic subdural hematoma, nutritional deficiencies (Wernicke-Korsakoff syndrome, Marchiafava-Bignami disease, pellagra, vitamin B₁₂ deficiency with subacute degeneration of the spinal cord and brain), chronic drug intoxication (e.g., alcohol, sedatives), certain endocrine-metabolic disorders (myxedema, Hashimoto thyroiditis encephalopathy, Cushing disease, chronic hepatic encephalopathy), some types of frontal and temporal lobe tumors, cerebral vasculitis, and, above all, the pseudodementia of depression. The dementia of AIDS and paraneoplastic limbic encephalitis may be partially amenable to treatment. Exclusion of these several diseases is most readily accomplished by sequential outpatient evaluations or by a brief admission to a hospital, where examinations of blood and CSF, EEG, CT, MRI, and neuropsychologic testing can be undertaken.

The most difficult problem in differential diagnosis, in the authors' experience, has been the distinction between a late-life depression and a dementia, especially when some degree of both is present. Multi-infarct dementia may be difficult to separate from Alzheimer dementia, since patients with the latter illness may have had one or more clinically ineventful infarcts. The dementia of normal-pressure hydrocephalus may also be confused with Alzheimer dementia. The differential diagnosis of these

several treatable conditions is discussed in [Chap. 21](#), [Chap. 30](#), [Chap. 34](#), and [Chap. 49](#). From time to time, we have been confident on clinical grounds that a patient had Alzheimer disease, only to have revealed at autopsy that progressive supranuclear palsy, Lewy body disease, Pick disease or another non-Alzheimer degeneration of the frontal lobes, or cortical-basal ganglionic degeneration was the cause. All of these are discussed later in this chapter.

Treatment There is no certain evidence that any of the proposed forms of therapy for Alzheimer disease—cerebral vasodilators, stimulants, L-dopa, massive doses of vitamins B, C, and E, and many others—has any salutary effect. Trials of oral physostigmine, choline, and lecithin have yielded mostly negative or uninterpretable results, and the same can be said for currently popular cholinergic precursors and agonists and acetylcholinesterase inhibitors, such as tacrine and donepezil, although there is some evidence of mild effect. The use of trazodone, haloperidol, thioridazine, risperidone, and related drugs may suppress some of the aberrant behavior and hallucinations when these are problems, making life more comfortable for both patient and family. Small doses of diazepam, such as lorazepam, are useful when sleep is severely disturbed.

The general management of the demented patient should proceed along the lines outlined in [Chap. 21](#), keeping in mind that the physician's counsel is often the family's main resource for medical and social issues.

Associated Pathologic States As indicated earlier, the histologic changes of Alzheimer disease have a number of interesting associations. The changes are far more common in the brains of patients with Parkinson disease than in the brains of age-matched controls ([Hakim and Mathieson](#)). As a corollary, large numbers of Lewy bodies (a characteristic feature of Parkinson disease) have been found in 10 percent of patients who had been diagnosed as having Alzheimer disease ([Woodard](#)). These findings at least partly explain the high incidence of dementia in patients with Parkinson disease (see further on, in the sections regarding Parkinson disease and Lewy body dementia), yet not more than 20 to 30 percent of patients with Parkinson disease have plaques and tangles. Another association between the two diseases is apparent in the *Guamanian Parkinson-dementia complex*, which is also discussed below. In this entity, the symptoms of dementia and parkinsonism are related to neurofibrillary changes in the cerebral cortex and substantia nigra, respectively; senile plaques and Lewy bodies are unusual findings.

There are rare instances, such as those reported by Malamud and Lowenberg and by Loken and Cyvin, in which dementia begins in late childhood, with the finding at postmortem examination of the typical Alzheimer lesions in the cerebral cortex and basal ganglia. The clinical picture in these juvenile and early adult cases has been more varied than in the older ones. In some, paucity of speech, mutism, tremor, stooped posture, marked grasp and suck reflexes, and pyramidal and cerebellar signs leading to inability to stand or walk have appeared at various stages of the disease.

The finding of neurofibrillary changes (and to a lesser extent of plaques) in boxers (“*punch-drunk*” syndrome, or “*dementia pugilistica*”) is another interesting ramification of the Alzheimer disease process (page 944). Hydrocephalus is present also, but there is insufficient information to determine whether it is a normal-pressure tension hydrocephalus from multiple subarachnoid hemorrhages or a hydrocephalus ex vacuo from cerebral atrophy.

Alzheimer disease in relation to the Down syndrome, first noted and reported by Jervis, is now widely recognized. The characteristic plaques and neurofibrillary tangles appear in the third decade; they increase with age and are present in practically all patients with the Down syndrome after 40 years of age.

The lobar sclerosis of Pick (see further on) has in some cases been associated with the histologic alterations of Alzheimer disease. A close relationship between Pick, Alzheimer, and Parkinson diseases has been demonstrated in a large family with dysphasic dementia ([Morris et al](#)). Other isolated combinations, wherein Alzheimer disease, hypothyroidism, hypopituitarism, or neurosyphilis were conjoined, were probably a matter of chance and prove nothing. From time to time other unusual associations come to light, such as *dementia with motor neuron disease* or the cases of *familial dementia with spastic paraplegia* reported by Worster-Drought and by van Bogaert and their associates (see further on in this chapter).

Lobar Atrophy (Pick Disease)

In 1892, Arnold Pick of Prague first described a special form of cerebral degeneration in which the atrophy is circumscribed (most often in the frontal and/or temporal lobes), with involvement of both gray and white matter—hence the term *lobar* rather than *cortical* sclerosis. In 1911, Alzheimer presented the first careful study of the microscopic changes. The most complete analyses of the pathologic changes are those of Spatz, van Mansvelt, Morris and coworkers, and Tissot and associates. Since the recognition of Pick disease rests more on pathologic than on clinical criteria, they are described first.

In contrast to Alzheimer disease, in which the atrophy is relatively mild and diffuse, the pathologic change in lobar atrophy is more circumscribed and sometimes asymmetrical. The atrophy may extend to the island of Reil and the amygdaloid-hippocampal structures. The parietal lobes are involved less frequently than the frontal and temporal lobes. The affected gyri become paper-thin; these parts of the brain resemble the kernel of a dried walnut. The cut surface reveals not only a markedly thinned cortical ribbon but a grayish appearance and reduced volume of the white matter. The corpus callosum and anterior commissure share in the atrophy. The overlying pia-arachnoid is thickened, and the ventricles are enlarged. The pre- and postcentral, superior temporal, and occipital convolutions are relatively unaffected and stand out in striking contrast to the wasted parts. Pick insisted that the disease essentially involves the association areas of Flechsig. In some instances, atrophy of the caudate nuclei has been pronounced, almost to the degree seen in Huntington chorea. The thalamus, subthalamic nucleus, substantia nigra, and globus pallidus may also be affected, but only to a slight degree.

The salient histologic feature of Pick disease is a loss of neurons, most marked in the first three cortical layers. Surviving neurons are often swollen, and some of them contain argentophilic (Pick) bodies within the cytoplasm. Ultrastructurally, the Pick bodies are made up of straight fibrils, thus differing from the paired helical filaments that characterize Alzheimer disease. These bodies predominate in the medial parts of the temporal lobes, especially in the atrophic hippocampi. “Ballooning” of cortical neurons is found mainly in the frontal cortex; in such cases, according to Tissot and others, atrophy of the basal ganglia and substantia nigra is especially frequent. There is a loss of myelinated fibers in the white matter beneath the atrophic cortex. A heavy astrocytic gliosis is seen in both the cortex and subcortical white matter. Most neuropathologists consider the loss of myelinated fibers to be consequent to neuronal loss. Senile plaques and Alzheimer neurofibrillary changes are seen in the atrophic zones in some of the cases (mixed Alzheimer and Pick disease), alluded to earlier, and there is granulovacuolar degeneration of neurons in the hippocampus, but not to the degree seen in Alzheimer disease.

The striking lobar cortical atrophy and changes in the white matter are readily visualized by CT scanning and MRI.

Clinical Features Whether the diagnosis of Pick disease can be made on purely clinical grounds is doubtful. Our predictions as to the existence of the pathologic changes and their differentiation from those of Alzheimer disease and the recently defined entity of “frontotemporal dementia” (described below) have been erratic, although they should improve with the use of stricter clinical criteria, CT scanning, and MRI. In our experience, the gradual onset of mental confusion with respect to place and time, anomia, slowness of comprehension, inability to cope with unaccustomed problems, loss of tact, deterioration of work habits, neglect of personal hygiene and grooming, apathy, and alterations of personality and behavior have been prominent features. In addition to personality changes, inability to perform sequences of motor tasks, motor perseveration, apathy (emotional indifference), inattention, abulia, impairment of gait and upright stance, and prominent grasp and suck reflexes are attributable to predominant affection of the frontal lobes.

Focal disturbances, particularly aphasia and apraxia, are said to occur early and to be prominent in patients with Pick disease, pointing to a lesion in the left frontal and temporal lobes. Early language disorder has been reported in two-thirds of all patients with temporal lobe atrophy. At first the patient speaks less but language is intact; later, he may forget and misuse words and soon fails to understand much of what is heard or read. Speech becomes a “medley of disconnected words and phrases” and eventually is reduced to an incomprehensible jargon. Finally, the patient is mute, seemingly without impulse to speak, and he loses the ability to form words ([Snowden et al](#)). Verbal perseveration, palilalia, and echolalia are frequent. Bulimia and alterations in sexual behavior occur to a distressing degree in some patients ([Tissot et al](#)).

Wilson distinguished two patterns of abnormal behavior: in one, the patient is talkative, lighthearted, cheerful or anxious, constantly on the move, occupied with trifles, and attentive to every passing incident; in the other, the patient is taciturn, inert, emotionally dull, and lacking in initiative and impulse. Probably these two patterns represent predominantly temporal and frontal types, respectively. According to Tissot and colleagues, the frontal, temporal, and parietal lobes are all affected in 75 percent of patients by the time the disease terminates.

The cause of Pick disease is unknown. Sjögren and associates concluded from a genetic survey of the cases in Stockholm that Pick disease was probably transmitted as a dominant trait with polygenic modification. A Dutch family with almost 100 percent penetrance over several generations has been reported by Schenk. Women seem to be affected more often than men. No chemical, vascular, traumatic, or other factor of possible causal importance has been identified.

The course of the illness is usually 2 to 5 years, occasionally longer, and nothing can be done therapeutically except to postpone the end by careful nursing.

Frontotemporal Dementia

This descriptive term has long been used by neurologists and neuropathologists to refer to any dementia that is associated with degeneration of the frontal and temporal lobes. Most such instances have proved to be examples of Alzheimer disease and, in lesser numbers, to Pick disease, as noted above. Also for many years, neuropathologists have been aware of instances of dementia that are identical clinically and in their gross pathology (gyral atrophy) to the Alzheimer and Pick types but do not show the characteristic histologic changes of either of these diseases. They do, however, exhibit tau-staining material in neurons of the affected regions. One source of abnormal (i.e., hyperphosphorylated) tau is from a mutation of the tau gene on chromosome 17; indeed, an abnormality of this gene is associated with such a frontotemporal dementia ([Basun et al](#)). But abnormal aggregates of tau have been identified in practically all neurodegenerative diseases and form the main constituent of the paired helical filaments (neurofibrillary tangles) of Alzheimer disease.

It appears from the observations of Brun and of Neary and their associates that pure tau-reactive cases actually outnumber Pick disease as strictly defined by the Pick inclusion, but the distinctions between the two have not always been clear from writings on the subject. Some of the clinical aspects are discussed in [Chap. 21](#), but, broadly speaking, the patients under discussion present the personality and behavioral abnormalities that would be expected from frontal and anterior temporal lobe dysfunction, such as apathy, perseveration, poor judgment and abstraction, bizarre affect, and a general disengagement. An initial diagnosis of depression is common. Other psychiatric symptoms—such as sociopathic and disinhibited behavior with aspects of hyperorality and hyperphagia—may predominate. (All of Wilson's comments, noted above in relation to Pick disease, pertain here as well.) Alternatively, aphasic or word-finding syndrome corresponding to a lateral temporal lobe degeneration may be the initial presenting and predominant feature, sometimes for several years, before other manifestations of dementia become evident.

In recent writings on this subject, the term *frontotemporal dementia* has come to be used in a highly restricted sense, being arbitrarily assigned to cases that show only tau-staining material in neurons. More such cases are sporadic, but an inherited variety linked to chromosome 17 has been described, in which parkinsonism is prominent; it is in these cases that the intraneural deposition of tau is most striking, in both the frontotemporal cortex and the substantia nigra.

Noteworthy also is the observation that a dementia identical to that of the tau-reactive cases occurs without any tau staining of neurons. Also, some of the frontally predominant cases have shown only marked vacuolation (microcavitation) of the affected cortex; cases of the latter type have been described in patients with amyotrophic lateral sclerosis (where tau staining has reportedly been found in the anterior horn cells).

The relationship between Pick disease and frontotemporal dementia is still uncertain. The clinical and gross pathologic findings—a regional frontotemporal atrophy of the cerebrum—are nearly identical in the two disorders. The main distinction is the presence or absence of Pick bodies or tau-staining material in neurons of the affected regions and greater affection of the white matter in Pick disease. If indeed the Pick and tau inclusions are shown in the future to be clearly distinctive biological changes, they can be considered to represent separate diseases, but many reported cases of sporadic lobar atrophy demonstrate both types of change, or what is even more confusing, neither type—making it impossible at this time to be certain of the purity of each type.

Other Degenerative Dementias

Diffuse Cerebral Atrophy of Non-Alzheimer Type There are other forms of progressive, diffuse brain atrophy leading to dementia that show none of the pathologic features of either Alzheimer or Pick disease or any of the other diseases that are sometimes associated with a dementing illness (Parkinson or Lewy body disease, amyotrophic lateral sclerosis, progressive supranuclear palsy, etc.).

In Sweden, for example, Sjögren has found familial cases of this type, as have Schaumburg and Suzuki in this country, and we have seen occasional sporadic examples. The clinical picture in these cases has been indistinguishable or has varied slightly from that of Alzheimer disease, and autopsy has disclosed widespread cerebral atrophy, most pronounced in the frontal lobes. Microscopically these cases are characterized by a diffuse neuronal loss, slight glial proliferation, and secondary demyelination of the white matter, like that observed with the frontal lobe atrophy of Pick disease. Other instances of sporadic and familial presenile dementia have shown subcortical gliosis or nonspecific cellular changes (atrophy of nerve cells and nuclei, loss of Nissl substance). Some examples of the latter type have in the past been described under the rubric of “Kraepelin disease” and more recently as “dementia lacking distinctive histologic features” ([Knopman et al](#)). Perhaps some or all of these cases will turn out to be a variant of the “tau” form of frontotemporal dementia, as discussed above.

Lewy Body Disease Another syndrome in which the dementia may be clinically indistinguishable from Alzheimer disease is one in which the cortical neurons contain Lewy bodies and in which neurofibrillary changes or senile plaques are less conspicuous or absent. Reports of Lewy body dementia have been increasing steadily since the original communication by Okazaki and others in 1961; many of these have been from Japan (see [Kosaka's](#) review). To some extent this is due to improved histologic techniques, particularly the immunoreactive ubiquitin and, more recently, synuclein stains, which enable one to visualize Lewy bodies in the cerebral cortex more clearly than before (see the discussion of Parkinson disease, which follows). The fact that aggregated α -synuclein makes up most of the Lewy body will undoubtedly prove important in relation to both Parkinson disease and Lewy body dementia. Next to Alzheimer disease and diffuse (non-Alzheimer) cerebral atrophy, diffuse Lewy body disease is thought to be the most common form of diffuse cerebral cortical atrophy with dementia.

Burkhardt and colleagues, in an analysis of 34 cases of diffuse Lewy body disease, found that the most characteristic syndrome was one of progressive dementia in an elderly patient with late onset of parkinsonian signs in some cases. For this reason, the disease also properly belongs in the category of dementias that are accompanied by other prominent neurologic features (page 1108). The movement disorder may be mild or prominent and may occur as an early or a late manifestation. In Lennox's summary of 75 cases published up to 1990, parkinsonism, particularly a limb and axial rigidity, was a prominent feature in 90 percent, and almost half had tremor. The parkinsonian features respond favorably to L-dopa, but for a limited time and sometimes at the expense of delirium or hallucinations ([Hely et al](#)). Some patients have orthostatic hypotension corresponding to cell loss and Lewy bodies in the intermediolateral cell column of the spinal cord or sympathetic ganglia.

Byrne and associates noted that episodic increases in confusion, hallucinations, and paranoid delusions were a feature of the Lewy body dementia; these psychotic features are generally uncharacteristic of Alzheimer and lobar dementias. In Lennox's review, one-third of patients with Lewy body dementia had these swings in behavior, but as the illness advanced, the amnesia, dyscalculia, visuospatial disorientation, aphasia, and apraxia did not differ from those of Alzheimer disease. In the cases of Fearnley and coworkers, there was a supranuclear gaze palsy simulating that of progressive supranuclear palsy. In our limited experience with Lewy body disease, the parkinsonian symptoms have been more prominent than in progressive supranuclear palsy; the most characteristic feature besides the movement disorder has indeed been intermittent psychotic or delirious behavior. Others have commented on an extreme sensitivity to neuroleptic drugs, including increased confusion and greatly worsening parkinsonism or the development of the neuroleptic malignant syndrome.

Thalamic Dementia A relatively pure degeneration of thalamic neurons has been described in relation to a progressive dementia ([Stern](#); [Schulman](#)). The dementia in these cases evolved relatively rapidly (several months) and was associated with choreoathetosis. Garcin and colleagues described five cases of subacutely developing dementia, which they considered to be examples of Creutzfeldt-Jakob disease; in each of them the pathologic changes consisted primarily of neuronal loss and gliosis of the thalamus. A large kindred of such cases, characterized by subacute dementia and myoclonus and inherited as an autosomal trait, has been reported by Little and coworkers. In members of this family, the clinical presentation was also very similar to that of Creutzfeldt-Jakob disease; however, the pathologic changes were confined to the thalami, particularly to the mediodorsal and other medial thalamic nuclei. Transmission of the disease to primates was unsuccessful.

In the *diagnosis* of this large category of chronic dementias, one must consider several nondegenerative disorders in which dementia may predominate and focal neurologic abnormalities may be minimal. Several of the treatable ones are listed in the discussion of Alzheimer disease, above, and a larger group is reviewed in [Chap. 21](#). Also to be considered, particularly in dementias with onset at an early age, are the inherited metabolic dis-eases discussed in [Chap. 37](#), the chief among which are the leukodystrophies—metachromatic, adrenal, globoid body (Krabbe disease)—and the poliodystrophies—neuronal ceroid lipofuscinosis (Kuf disease), GM₂ gangliosidosis, and Wilson disease (see page 1026). Each of these displays characteristic neurologic features, but each may present in the early stages with a decline in intellectual function and a behavioral disorder.

Finally, a brief comment is required regarding the group of diseases called “vascular dementia,” listed in many classifications as the second most common cause of mental decline after Alzheimer disease. As discussed in [Chap. 34](#), multiple cortical strokes may cause increasing deficits that cumulatively qualify as a dementia, but each element of focal cerebral disease that contributes to the cognitive decline can be identified, and a stepwise decline that corresponds to the abrupt onset of each

stroke is evident. A more difficult problem arises in a limited number of patients who have a multitude of deep lacunar infarctions. Their mental capacities may appear to decline slowly, although memory is not involved disproportionately, and usually a pseudobulbar state or one of the other characteristic lacunar stroke syndromes can be identified, so there is little trouble in differentiation from the degenerative dementias. The subcortical white matter change of Binswanger disease causes similar diagnostic problems, as discussed on pages 451 and 878. Beyond these vascular diseases and the familial CADASIL disease (cerebral autosomal dominant arteriopathy with subcortical infarcts, page 878), which is of uncertain cause, the authors are dubious of the category of vascular dementia. Most cases turn out to be Alzheimer disease with one or more visible infarctions.

DISEASES IN WHICH DEMENTIA IS ASSOCIATED WITH OTHER NEUROLOGIC ABNORMALITIES

Huntington Chorea

This disease, distinguished by the triad of dominant inheritance, choreoathetosis, and dementia, commemorates the name of George Huntington, a medical practitioner of Pomeroy, Ohio. In 1872, in a paper read before the Meigs and Mason Academy of Medicine and published later that year in the *Medical and Surgical Reporter* of Philadelphia, Huntington gave a succinct and graphic account of the disease, based on observations of patients that his father and grandfather had made in the course of their practice in East Hampton, Long Island. Reports of this disease had appeared previously (see [DeJong](#), in the References, for historical background), but they lacked the accuracy and completeness of Huntington's description. Vessie, in 1932, was able to show that practically all the patients with this disease in the eastern United States could be traced to about six individuals who had emigrated in 1630 from the tiny East Anglian village of Bures, in Suffolk, England. One remarkable family was traced for 300 years through 12 generations, in each of which the disease had expressed itself.

To quote Huntington, the rule has been that “When either or both of the parents have shown manifestations of the disease . . . one or more of the offspring invariably suffer of the disease, if they live to adult life. But if by any chance these children go through life without it, the thread is broken and the grandchildren and great-grandchildren of the original shakers may rest assured that they are free from disease.” Davenport, in a review of 962 patients with Huntington chorea, found only 5 who had descended from unaffected parents. Possibly, in these latter patients, a parent had the trait, but in very mild form. Or, one or more of these patients represented rare sporadic instances of Huntington chorea, i.e., individuals in whom a mutation had occurred from a normal gene to the mutant, disease-producing form.

In university hospital centers, this is one of the most frequently observed types of hereditary nervous system disease. Its overall frequency is estimated at 4 to 5 per million, and 30 to 70 per million among whites of northern European ancestry. The usual age of onset is in the fourth and fifth decades, but 3 to 5 percent begin before the 15th year and some even in childhood. In about 30 percent, symptoms become apparent after 50 years. The progression of the disease is slower in older patients. Once begun, the disease progresses relentlessly, until only a restricted existence in a nursing home or psychiatric hospital is possible and some other disease terminates life.

Exhaustive genealogic documentation has established the cause to be an autosomal dominant gene with complete penetrance (see below). Martin has made the observation that young patients usually inherit the disease from their fathers and older patients from their mothers. It has been observed beginning at almost the same age in identical twins.

Until recently, it had not been possible to foretell which of the children of a patient will be stricken with the disease. Caudate glucose metabolism—measured by positron emission tomography (PET) in earlier studies—although reduced in most presymptomatic patients, proved not to be a sufficiently dependable indicator of persons at risk for Huntington disease. The most important achievement in respect to the presymptomatic detection of Huntington disease was the discovery, by Gusella and colleagues, of a marker linked to the Huntington gene, localized to the short arm of chromosome 4. Subsequently these investigators and others identified the gene abnormality as an excessively long repeat of trinucleotides (CAG), the length of which determines not only the presence of the disease but also the age of onset. This discovery has made possible the development of a test for the detection of the defective gene in asymptomatic individuals. In view of the fact that there is no treatment for the disease, testing raises certain ethical considerations that need to be resolved before its widespread utilization.

Clinical Features *The mental disorder* assumes several subtle forms long before the more obvious deterioration of cognitive functions becomes evident. In approximately half the cases, slight and often annoying alterations of character are the first to appear. Patients begin to find fault with everything, to complain constantly, and to nag other members of the family; they may be suspicious, irritable, impulsive, eccentric, untidy, or excessively religious, or they may exhibit a false sense of superiority. Poor self-control may be reflected in outbursts of temper, fits of despondency, alcoholism, or sexual promiscuity. Disturbances of mood, particularly depression, are common (almost half of the patients in some series) and may constitute the most prominent symptoms early in the disease. Invariably, sooner or later, the intellect begins to fail. The patient becomes less communicative and more socially withdrawn. These emotional disturbances and changes in personality may reach such proportions as to constitute a virtual psychosis (with persecutory delusions or hallucinations).

Diminished work performance, inability to manage household responsibilities, and disturbances of sleep may prompt medical consultation. There is difficulty in maintaining attention, in concentration, and in assimilating new material. Mental flexibility lessens. There is loss of fine manual skills (see further on). The performance parts of the Wechsler Adult Intelligence Scale show greater loss than the verbal parts. Memory is relatively spared. This gradual dilapidation of intellectual function has been characterized as a “subcortical dementia” (page 450), i.e., elements of aphasia, agnosia, and apraxia are observed only rarely and memory loss is not profound. Often the process is so slow that some degree of intellectual capacity is retained for many years.

The *abnormality of movement* is at first slight and most evident in the hands and face; often the patient is merely considered to be fidgety, restless, or “nervous.” Slowness of movement of the fingers and hands, a reduced rate of finger tapping, and difficulty in performing a sequence of hand movements are early motor signs. Gradually these abnormalities become more pronounced until the entire musculature is implicated. The frequency of blinking is increased (the opposite of parkinsonism), and voluntary protrusion of the tongue is constantly interrupted by unwanted darting movements. In the advanced stage of the disease, the patient is seldom still for more than a few seconds. The movements are slower than the brusque jerks and postural lapses of Sydenham chorea, and they involve many more muscles. They tend to recur in stereotyped patterns yet are not as stereotyped as tics. In more advanced cases, they acquire an athetoid or dystonic quality. Muscle tone is usually decreased until late in the illness, when there may also be some degree of rigidity, tremor, and bradykinesia, elements suggestive of Parkinson disease (Westphal or “rigid” variant, which is more common with a childhood onset). Tendon reflexes are exaggerated in one-third of patients, but only a few have Babinski signs. Voluntary movements are initiated and executed more slowly than normal, but there is no weakness and no real ataxia, although speech, which becomes dysarthric and explosive due to incoordination between tongue and diaphragm, may convey the impression of a cerebellar disorder. There is poor control of the tongue and diaphragm. Denny-Brown pointed out that when the Huntington patient is suspended, the upper limbs assume a flexed posture and the legs an extended one, a posture that he considered to be expressive of the striatal syndrome. The disorder of movement that characterizes Huntington chorea is described more fully in [Chap. 4](#). Oculomotor function is affected in most patients ([Leigh et al](#); [Lasker et al](#)). Particularly characteristic are impaired initiation and slowness of pursuit and volitional saccadic movements and an inability to make a volitional saccade without movement of the head. Excessive distractibility may be noticed during attempted ocular fixation. The patient feels compelled to glance at extraneous stimuli even when specifically instructed to ignore them. Upward gaze is often impaired.

As Wilson stated, the relation of the choreic to the mental symptoms “abides by no general rule.” Most often the mental symptoms precede the chorea, but they may accompany or follow it, sometimes by many years. In our own material, with two exceptions of late onset with rigidity rather than chorea, once the movement disorder was fully established, there was nearly always some degree, perhaps slight, of cognitive abnormality. Exceptional cases have been reported, in which the movement disorder existed for 10 to 30 years without mental changes in patients with the gene abnormality of Huntington disease ([Britton et al](#)). After 10 to 15 years, most patients deteriorate to a vegetative state, unable to stand or walk and eating little; in this late stage, a mild amyotrophy may appear. Noteworthy is the high suicide rate in huntingtonians, as pointed out by Huntington ([Schoenfeld et al](#)). Also, there is a high incidence of trauma; chronic subdural hematoma is a common finding at autopsy.

The first signs of the disease may appear in childhood, before puberty (even under the age of 4), and several series of such cases have been described ([Farrer and Conneally](#); [van Dijk et al](#)). Mental deterioration at this early age is more often accompanied by cerebellar ataxia, behavior problems, seizures, bradykinesia, rigidity, and dystonia than by chorea ([Byers et al](#)). However, this rigid form of the disease (Westphal variant) is known also to occur occasionally in adults, as mentioned above. Functional decline is much faster in children than it is in adults ([Young et al](#)).

Earlier onset in successive generations (*anticipation*) is well described in the early writings on the subject and is now known to be attributable to increasing lengths of the CAG repeat sequence, as already pointed out. The dementia is generally more severe in cases of early onset (15 to 40 years) than in those of later onset (55 to 60 years).

At the gene locus implicated in Huntington disease there are normally 11 to 34 (median 19) consecutive repetitions of the CAG triplet that codes for glutamine; individuals with more than 35 to 39 triplets may have the disease and those with more than 42 invariably acquire the signs of disease if they live long enough. As already noted, the CAG repeat length correlates with disease severity, the early-onset cases having the largest number of repeats. Furthermore, in adult patients with early onset of the disease, the emotional disturbance tends to be initially prominent and precedes the chorea and intellectual loss by many years; with older age of onset, choreiform movements and progressive dementia are more often the initial components and have their onset at nearly the same age.

Pathology and Pathogenesis Gross atrophy of the head of the caudate nucleus and putamen bilaterally is the characteristic abnormality, usually accompanied by a moderate degree of gyral atrophy in the frontal and temporal regions. The caudatal atrophy alters the configuration of the frontal horns of the lateral ventricles; the inferolateral borders do not show the usual bulge formed by the head of the caudate nucleus; in addition, the ventricles are diffusely enlarged ([Fig. 39-2](#)). In CT scans, the bicaudate-cranial ratio is increased in the majority of patients. This finding corroborates the clinical diagnosis in the moderately advanced case.

Figure 39-2 The upper CT scan is from a 54-year-old mildly demented woman with a 10-year history of Huntington chorea. The bulge in the inferolateral border of the lateral ventricle, normally created by the head of the caudate nucleus (lower scan from a patient of the same age for comparison), has been obliterated. There is also a diffuse enlargement of the lateral ventricles.

The early articles of Alzheimer and Dunlap and the more recent one of Vonsattel and DiFiglia contain the most authoritative descriptions of the microscopic changes. The latter authors have graded the disease into early, moderately advanced, and far advanced stages. In five genetically verified early cases, no striatal lesion was found, which suggests that the first clinical manifestations are based on a biochemical disorder without visible structural change, at least by light microscopy. This view is supported by the observation that Huntington patients studied with PET show a characteristic decrease in glucose metabolism, which appears early in the disease and precedes the loss of tissue ([Hayden et al](#)). The striatal degeneration begins in the medial part of the caudate nucleus and spreads, tending to spare the nucleus accumbens. Of the six cell types in the striatum (differentiation based on size, dendritic arborizations, spines, and axon trajectories), the smaller cells are affected before the larger ones. Loss of dendrites of the small spiny neurons has been an early finding. The large cells are relatively preserved and exhibit no special alterations. The lost cells are replaced by fibrous astrocytes. With neuronal loss, the myelinated fibers also disappear. The anterior parts of the putamen and caudatum are more affected than the posterior parts. In our own cases we have not been impressed with changes in the globus pallidus, subthalamic nucleus, red nucleus, or cerebellum, but others have observed slight changes in these parts and in the pars reticulata of the substantia nigra. In the cerebral cortex, there is said to be slight neuronal loss in layers 3, 5, and 6, with replacement gliosis. Cases are reported with typical striatal lesions but normal cortices, in which only chorea had been present during late life. In our early to moderately advanced cases, even quantitative analyses of the cortex have not disclosed a significant loss of neurons. Several neuropathologists have observed marked cell loss and gliosis in the subthalamic nuclei in children or young adults with chorea and behavior disorders.

The biochemical defects in Huntington chorea are only beginning to be understood. The impaired glucose metabolism in the caudate nucleus, preceding visible atrophy, has already been mentioned. Since at least a partial explanation for L-dopa–induced involuntary movements is an excess of dopamine (in contrast to Parkinson disease, in which there is a decrease), it has been postulated that the abnormal movements of Huntington chorea represent a heightened sensitivity of striatal dopamine receptors. There are disturbances in the metabolism of other putative neurotransmitters (norepinephrine, glutamic acid decarboxylase, choline acetyltransferase, GABA, acetylcholine, and somatostatin), but the significance of these biochemical disturbances is unknown.

The product of the Huntington gene locus has been termed *huntingtin* and its mutated form contains an excessive number of glutamine residues as a result of the excess copies of the CAG nucleotide. Although the function of the protein is not known, an excess of huntingtin accumulates in the nuclei of neurons in human disease and in transgenic mice with an increased number of CAG repeats. Moreover, the protein accumulates in cells of the striatum and parts of the cortex affected in Huntington disease.

Diagnostic Problems Once the disease has been observed in its fully developed form, its recognition requires no great clinical acumen. The main difficulty arises with patients who lack a family history but in whom the progressive chorea, emotional disturbance, and dementia with onset in adult life are typical. This difficulty has been largely overcome since the mutation causing Huntington disease was identified. It is now possible to confirm or exclude the diagnosis by analysis of DNA from a blood sample, the presence of greater than 39 to 42 CAG repeats at the Huntington locus essentially confirming its presence; lesser numbers leave room for equivocation. Sometimes it is learned later that the family history was incomplete or falsified or that an illness in a parent had been misinterpreted. Chorea that begins in late life, with only mild or questionable intellectual impairment and without a family history of similar disease, is another source of difficulty; referring to it as senile chorea does not solve the problem. Indeed, senile chorea may have more than one cause. We have seen it appear with infections, drug therapy, and thyrotoxicosis, only to disappear after a few weeks. *Chorea in early adult life* always raises the question of a late form of Sydenham chorea or of lupus erythematosus with antiphospholipid antibodies, but neither familial occurrence nor mental deterioration is part of these diseases. Other progressive neurologic disorders that are inherited as autosomal dominant traits and begin in adolescence or adult life (e.g., polymyoclonus with or without ataxia, acanthocytosis with progressive chorea, and especially dentatorubropallidolusian degeneration) can closely mimic Huntington disease, as described further on, and sometimes only the pathologic picture settles the matter.

Other problems in differential diagnosis include bilateral thalamic degeneration with dementia and chorea, referred to earlier; paroxysmal choreoathetosis (page 83); Wilson disease (page 1026); acquired hepatocerebral degeneration (page 1195); and, most often, schizophrenia or manic-depressive psychosis complicated by tardive dyskinesia (page 1264). Many drugs in addition to L-dopa occasionally cause chorea (amphetamines, tricyclic antidepressants, lithium, isoniazid).

Therapy The dopamine antagonist haloperidol, in daily doses of 2 to 10 mg, is probably the most effective agent in suppressing the movement disorder. Because of the danger of superimposing tardive dyskinesia on the chronic disorder, the chorea should be treated only if it is functionally disabling, using the smallest possible dosages and providing numerous drug holidays. Haloperidol may also help alleviate abnormalities of behavior or emotional lability, but it does not alter the progress of the disease. The authors have not been impressed with the therapeutic effectiveness of other currently available drugs. Levodopa and other dopamine agonists make the chorea worse and, in the rigid form of the disease, evoke chorea. Drugs that deplete dopamine or block dopamine receptors—such as reserpine, clozapine, and tetrabenazine—suppress the chorea to some degree, but their side effects (drowsiness, akathisia, and tardive dyskinesia) outweigh their desired effects. The juvenile (rigid) form of the disease is probably best treated with antiparkinsonian drugs. Huntington disease pursues a steadily progressive course and death occurs, on an average, 15 to 20 years after onset, sometimes much earlier or later. The psychologic and social consequences of the disease require supportive therapy, and genetic counseling is essential.

Acanthocytosis with Chorea

A few reports of a slowly progressive familial chorea and dementia in association with an abnormality of erythrocytes have appeared in English, American, and Japanese journals. The disease has the following characteristics: (1) onset in adolescence or early adult life of generalized involuntary movements (described as chorea but including dystonia and tics), usually beginning as an orofacial dyskinesia and spreading to other parts of the body; (2) mild to moderate mental deterioration in some but not all of the cases; (3) decreased or absent tendon reflexes and evidence of chronic axonal neuropathy and denervation atrophy of muscles; (4) atrophy and gliosis of the caudate nuclei and putamens but no neuronal loss in the cerebral cortex or other parts of the brain; and (5) acanthocytosis (thorny or spiky appearance of erythrocytes). The last change, according to Sakai and coworkers, is due to an abnormal composition of covalently (tightly) bound fatty acids in erythrocyte membrane proteins (palmitic and docosahexanoic acids increased and stearic acid decreased). The pattern of inheritance has been autosomal

recessive but was dominant in one New England family. The acanthocytosis may be overlooked when it is mild but can be detected by scanning electron microscopy. In the series of 19 cases reported by Hardie and colleagues, the manifestations included dystonia, tics, vocalizations, rigidity, and lip and tongue biting; more than half had cognitive impairment or psychiatric features. The average age of onset was 32 years; 7 of the 19 cases were sporadic. The disease has been linked in almost all families to chromosome 9q. The so-called McLeod phenotype differs hematologically in that there is an abnormal expression of Kell surface antigens on the erythrocyte.

Several *other rare degenerative disorders with chorea*, some of which have already been mentioned, fall into this category. Midlife progressive chorea without dementia (after more than 25 years follow-up) has been reported. There was no abnormality of chromosome 4. *Dentatorubropallidoluysian atrophy*, diagnosed clinically as Huntington chorea, was found in four European families by Warner and associates and is described further on in the section on cerebellar degenerations. The extrapyramidal manifestations included chorea, myoclonus, and rigidity. Adult-onset chorea and dementia have been described with *propionic acidemia*; propionic acid was elevated in the plasma, urine, and CSF. This disorder must be added to other metabolic diseases described in [Chap. 37](#) as causes of chorea and dyskinesia—such as glutaric acidemia, keratin sulfaturia, calcification of basal ganglia, and Hallervorden-Spatz disease ([Hagberg et al](#)).

Corticostriatospinal Degenerations

Included in this category are a number of degenerative diseases in which the symptoms of dementia, parkinsonism, and amyotrophic lateral sclerosis present in various combinations. Some of the diseases that make up this group have not been sharply delineated and are difficult to separate from one another (see also page 1140).

Under the title “spastic pseudosclerosis,” Jakob, in 1921, described a chronic disease of middle to late adult life, characterized by abnormalities of behavior and intellect; weakness, ataxia, and spasticity of the limbs (chiefly the legs); extrapyramidal symptoms such as rigidity, slowness of movement, tremors, athetotic postures, and hesitant, dysarthric speech; and normal spinal fluid. The pathologic changes were diffuse and consisted mainly of an outfall of neurons in the frontal, temporal, and central motor gyri, corpus striatum, ventromedial thalamus, and bulbar motor nuclei. In one of Jakob's cases, there were also prominent changes in the anterior horns and corticospinal tracts in the spinal cord like those of amyotrophic lateral sclerosis (ALS). The latter find-ing gave rise to Wilson's concept of the disease as a *corticostriatospinal degeneration*. A degenerative and probably familial disorder that had been described earlier by Creutzfeldt was considered by Spielmeyer to be sufficiently similar to the one of Jakob to warrant the designation Creutzfeldt-Jakob disease.

As discussed in [Chap. 33](#), the disorder described by Creutzfeldt and Jakob has been a source of endless controversy because of its indeterminate character. On the one hand, it has been confused with the subacutely evolving myoclonic dementia, “subacute spongiform encephalopathy,” which is now known to be an infection due to an unconventional transmissible agent (prion). The authors believe that the latter disease, which is described on page 814, bears at best only a superficial resemblance to the one described by Creutzfeldt and Jakob, and that the two disorders should be clearly separated. Unfortunately, the eponym is so entrenched in medical usage that any attempt to remove it stands little chance of success. On the other hand, sporadic and familial cases that are not transmissible and lack a prominent spongiform change merge with a rather heterogeneous but overlapping group of degenerative disorders, all rare, including progressive dementia and spastic paraplegia, progressive dementia and ALS, the Parkinson-dementia-ALS complex of Guam, and the corticopallidospinal degeneration of Davison.

Other variants of this category of disease continue to appear. The authors have observed several patients in whom extreme rigidity, corticospinal signs, and evidence of ALS have developed over a period of several years. In the later stages of the disease, the patient, while alert, is totally helpless—unable to speak, swallow, or move the limbs. Only eye movements are retained, and even these are hampered by supranuclear gaze palsies in advanced cases. Intellectual functioning appears to be better preserved than movement but is difficult to assess. Other bodily functions are intact. The course is slowly progressive and ends fatally in 5 to 10 years. There is no family history of similar disease, and there are no clues as to causation. Gilbert and colleagues have described similar cases with signs of Parkinson disease, motor neuron disease, and dementia; in their cases, there were no senile plaques or Lewy bodies. The concurrence of typical motor neuron disease and Parkinson disease may be coincidental, but Qureshi and colleagues described 13 patients in whom both disease processes began within a brief time of one another and considered them to be related. In the variant described by Tandan and colleagues, an autosomal dominant syndrome of Charcot- Marie-Tooth polyneuropathy was combined with ptosis, Parkinson syndrome, and dementia, again without Lewy bodies or senile plaques. Yet other variants have been described by Schmitt and coworkers and by Mata and colleagues. Hudson has reviewed 42 sporadic cases in which ALS-parkinsonism-dementia were combined (see [References](#)).

The *Guamanian Parkinson-dementia-ALS* complex deserves separate comment because it constitutes a large number of carefully studied cases with almost uniform clinical and pathologic features. The disease occurs in the indigenous Chamorro peoples of Guam and the Mariana islands, predominantly in men between ages 50 and 60. Progressive parkinsonism and dementia are combined with upper or lower motor neuron disease (ALS is also common among the Chamorro), leading to death in 5 years. The pathologic changes, described by Hirano and others, consist of severe cortical atrophy with neurofibrillary tangles but, conspicuously, no plaques are detectable, even with sensitive neurochemical staining. As in Parkinson disease, the substantia nigra and to a lesser extent other pigmented nuclei are depopulated of nerve cells but contain no Lewy bodies. Cases with amyotrophy show an appropriate anterior horn cell loss.

One is tempted to conclude that the spastic pseudosclerosis of Jakob should not be considered as a disease type, and certainly everyone agrees that the term *pseudosclerosis* (also used for the Westphal-Strümpell form of hepatolenticular degeneration) is meaningless.

Familial Dementia with Spastic Paraparesis

From time to time the authors have encountered families in which several members developed a spastic paraparesis and a gradual failure of intellect during the middle adult years. The mental horizon of the patient narrowed gradually, and the capacity for high-level thinking diminished; in addition, the examination showed appropriately exaggerated tendon reflexes, clonus, and Babinski signs. In one such family the illness had occurred in two generations; in another, three brothers in a single generation were afflicted. Skre described two recessive types of hereditary spastic paraplegia in Norway, one with onset in childhood, the other in adult life. In contrast to the dominant form (see further on), the recessive types displayed evidence of more widespread involvement of the nervous system, including dementia, cerebellar ataxia, and epilepsy. Also, Cross and McKusick have observed a recessive type of paraplegia accompanied by dementia beginning in adolescence. They named it the *Mast syndrome*, after the afflicted family.

Worster-Drought and others have reported the pathologic findings in two cases of this type. In addition to senile plaques and neurofibrillary changes, there was demyelination of the subcortical white matter and corpus callosum and a “patchy but gross swelling of the arterioles,” which gave the staining reactions for amyloid (“Scholz's perivascular plaques”). Van Bogaert and associates published an account of similar cases that showed the characteristic pathologic features of Alzheimer disease.

Adult forms of metachromatic leukodystrophy and adrenoleukodystrophy may present with a similar clinical picture ([Chap. 37](#)). Another interesting association of familial spastic paraplegia is with progressive cerebellar ataxia. Fully one-third of the cases that we have seen with such a spastic weakness were also ataxic and would fall into the category of spinocerebellar degenerations. Yet another variant of this group of diseases has been described by Farmer and colleagues; the inheritance in their cases was autosomal dominant, and the main clinical features were deafness and dizziness, ataxia, chorea, seizures, and dementia, evolving in that order. Postmortem examinations of two patients disclosed calcification in the globus pallidus, neuronal loss in the dentate nuclei, and destruction of myelinated fibers in the centrum semiovale.

Adult Polyglucosan Body Disease

Under this title Robitaille and colleagues described a distinct type of progressive neurologic disease in adults, characterized clinically by spasticity, chorea, dementia, and a predominantly sensory polyneuropathy. Structures that closely resembled Lafora bodies and corpora amylacea were found in large numbers in both central and peripheral neural processes (mainly in axons) and also in astrocytes. These basophilic, periodic acid–Schiff (PAS)–positive structures, up to 40 mm in size, were made up of glucose polymers (polyglucosans) and were readily apparent in sural nerve biopsies. Some were found in the heart and liver.

More recently, Rifal and associates have reviewed the findings in 25 cases of this disease—one observed personally and 24 that had been reported previously. The dementia appears to be relatively mild, consisting of impairment of retentive memory, dysnomia, dyscalculia, and sometimes expressive dysphasia and deficits of “visual integration”; this is overshadowed by the rigidity and spasticity of the limbs and the peripheral nerve disorder. Nerve conduction velocities are diminished and leg muscles are denervated. Moderate degrees of generalized cerebral atrophy, multifocal areas of white matter rarefaction, and increased iron deposition in the putamina are disclosed by MRI. The finding of polyglycosan axon inclusion in biopsied nerve confirms the diagnosis. The disease was sometimes misdiagnosed as

adrenoleukodystrophy.

DISEASES CHARACTERIZED BY ABNORMALITIES OF POSTURE AND MOVEMENT

Parkinson Disease (Paralysis Agitans)

This common disease, known since ancient times, was first cogently described by James Parkinson in 1817. In his words, it is characterized by “involuntary tremulous motion, with lessened muscular power, in parts not in action and even when supported; with a propensity to bend the trunk forward, and to pass from a walking to a running pace, the senses and intellect being uninjured.” Strangely, his essay contains no reference to rigidity or to slowness of movement, and it stresses unduly the reduction in muscular power. The same criticism can be leveled against the term *paralysis agitans*, which appeared for the first time in 1841, in Marshall Hall's textbook *Diseases and Derangements of the Nervous System*.

Certain aspects of the natural history of the disease are of interest. As a rule, it begins between 40 and 70 years of age, with the peak age of onset in the sixth decade. It is infrequent before 30 years of age (only 4 of 380 cases in one series), and most series contain a somewhat larger proportion of men. Trauma, emotional upset, overwork, exposure to cold, “rigid personality,” and so on, among many other factors, have been suggested as predisposing to the disease, but there is no convincing evidence to support any such claims. The possible relationship to repeated cerebral trauma and to the “punch-drunk” syndrome (dementia pugilistica, page 944) has been particularly problematic and is unresolved despite the documentation provided by several celebrated cases ([Lees](#)). Idiopathic Parkinson disease is observed in all countries, all ethnic groups, and all socioeconomic classes, although the incidence in blacks is only one-quarter that in whites; in Asians, the incidence is one-third to one-half that in whites. A lack of concordance of Parkinson disease in twins appears to negate the role of genetic factors, but a study of dopamine metabolism utilizing PET scanning has shown that 75 percent of asymptomatic twins of Parkinson patients had evidence of striatal dysfunction and only a small portion of dizygotic twins showed these changes ([Piccini et al](#)). These data suggest a more substantial role for an inherited trait in cases of ostensibly sporadic disease. Also, Krüger and colleagues have reported a 13-fold increased susceptibility to the disease in patients who harbor a combination of a-synuclein and apolipoprotein E genotypes (see below).

While familial cases are decidedly rare, Golbe and colleagues have described two large kindreds (probably related and originating from a small town in southern Italy) in which 41 patients in four generations were affected. The illness in their cases was characteristic of Parkinson disease both clinically and pathologically, the only unusual features being a somewhat earlier onset (mean age 46 years), a relatively rapid course (10 years from onset to death), and a reported incidence of tremor in only 8 of the 41 patients. The dominantly inherited parkinsonism described by Dwork and others also differed clinically (onset in third decade, prominence of dystonia) and pathologically (absence of Lewy bodies) from classic Parkinson disease. It was in the latter kindred and in three Greek families that Polymeropoulos et al identified a locus on chromosome 4q that contained a mutation for a-synuclein, a main component of the Lewy body. Other families in which there have been mendelian patterns of inheritance are associated with gene defects at other sites (but still mostly on chromosome 4). These genetic data have been reviewed by Dunnett and Björklund.

The disease is common. In North America there are approximately 1 million patients, constituting about 1 percent of the population over the age of 65 years. The incidence in all countries where vital statistics are kept is similar. Considering its frequency, coincidence in a family on the basis of chance occurrence might be as high as 5 percent.

Clinical Features The core syndrome of expressionless face, poverty and slowness of voluntary movement, “resting” tremor, stooped posture, axial instability, rigidity, and festinating gait has been fully described in [Chap. 4](#), and only certain diagnostic problems and variants in the clinical picture need to be considered here. The early symptoms may be difficult to perceive and are often overlooked. Advancing years have a way of rendering the spine and limbs less pliable and elastic, and in the senium the gait may become short-stepped and then reduced to a shuffle. The voice tends to become soft and monotonous. Hence it is all too easy to attribute the early symptoms of Parkinson disease to the effects of aging. For a long time the patient may not be conscious of the inroads of the disease; at first the only complaints may be of aching of the back, neck, shoulders, or hips and of vague weakness. A slight stiffness and slowness of movement or a reduction in the natural swing of one arm during walking are ignored, until one day it occurs to the physician or to a member of the family that the patient has Parkinson disease. Infrequency of blinking, as pointed out originally by Pierre Marie, is often a helpful early sign. The usual rate (12 to 20 blinks per minute) is reduced in the parkinsonian patient to 5 to 10. And with it there is a slight widening of the palpebral fissures, creating a stare (Stellwag sign). A reduction in movements of the small facial muscles imparts the characteristic expressionless (“masked”) appearance (hypomimia). When seated, the patient makes fewer small shifts and adjustments of position than the normal person (hypokinesia), and the fingers straighten and assume a flexed and adducted posture at the metacarpophalangeal joints.

The characteristic tremor, which usually involves a hand, is often listed as the initial sign; but in at least half the cases, observant family members will have remarked earlier on the patient's relative immobility and poverty of movement. Moreover, in 20 to 25 percent of cases the tremor is mild and intermittent or evident in only one finger or one hand. The tremor of the fully developed case takes several forms, as was remarked in [Chap. 6](#). The 4-per-second “pill-rolling” tremor of the thumb and fingers is seen in only a small proportion of patients and is typically present when the hand is motionless, i.e., not used in voluntary movement (hence the term *resting tremor*). Complete relaxation, however, greatly reduces or abolishes the tremor, and a volitional movement usually but not always dampens it momentarily. The rhythmic beat coincides with an alternating burst of activity in agonists and antagonists in the electromyogram (EMG). The arm, jaw, tongue, eyelids, and foot are less often involved. The least degree of tremor is felt during passive movement of a rigid part (cogwheel phenomenon or Negro's sign). The tremor shows surprising fluctuations in severity and is aggravated by walking and excitement, but tremor frequency remains constant ([Hunker and Abbs](#)). *One side of the body is typically involved before the other*, and the tremor then remains asymmetrical as the illness advances.

Lance and associates have called attention to another common type of tremor in Parkinson disease—a fine, 7- to 8-per-second, slightly irregular action tremor of the outstretched fingers and hands. This tremor, unlike the slower one, persists throughout voluntary movement, is not evident with the limb in a resting position, and is more easily suppressed by relaxation. Electromyographically, it lacks the alternating bursts of action potentials seen in the more typical tremor. The patient may have either type of tremor or both.

We have been less impressed with rigidity and hypertonus as important early findings. They tend to appear in the more advanced stages of the disease. Once rigidity develops, it is constantly present; it can be felt by the palpating finger and seen as a salience of muscle groups even when the patient relaxes. When the examiner passively moves the limb, a mild resistance appears from the start (without the short free interval that characterizes spasticity), and it continues evenly throughout the movement, in both flexor and extensor groups, being interrupted only by the cogwheel phenomenon. Both the rigidity and its cogwheel feature can be elicited by having the patient occupy the opposite limb with a motor task requiring some degree of concentration, such as tracing circles in the air or touching each finger to the thumb. Postural hypertonus predominates in the flexor muscles of trunk and limbs and confers upon the patient the characteristic flexed posture. Particulars of the parkinsonian disorders of muscle tone, stance, and gait are discussed further in [Chap. 4](#) and [Chap. 7](#).

Regarding the quality of volitional and postural movements, a few additional points should be made. The patient is slow and ineffective in attempts to deliver a quick hard blow; he cannot complete a quick (ballistic) movement by a single burst of agonist-antagonist-agonist sequence of energizing activity, like the normal person; several bursts are needed ([Hallett and Khoshbin](#)). Alternating movements, at first successful, become progressively impeded and finally are blocked completely or adopt the rhythm of the patient's tremor. Also, the patient has difficulty in executing two motor acts simultaneously. Originally the impaired facility of movement was attributed to rigidity, but the observation that appropriately placed surgical lesions can abolish rigidity without affecting the disorder of movement refutes this interpretation. Thus the difficulty is not one of rigidity but one of *bradykinesia* (slowness in both the initiation and execution of movement), the extreme degree of which is akinesia. The latter deficits underlie the characteristic poverty of movement, shown by infrequency of swallowing, slowness of chewing, a limited capacity to make postural adjustments of the body and limbs in response to displacement of these parts, a lack of small “movements of cooperation” (as in arising from a chair without first adjusting the feet), absence of arm swing in walking, etc. Despite a perception of muscle weakness, the patient is able to generate normal or near-normal power, especially in the large muscles; however, in the small ones, strength is slightly diminished.

As the disorder of movement worsens, all customary activities show the effects. Handwriting becomes small (micrographia), tremulous, and cramped, as first noted by Charcot. The voice softens and the speech seems hurried and monotonous; the voice becomes less audible and finally the patient only whispers. Exceptionally, “mumbling” is an early complaint. Caekebeke and coworkers refer to the speech disorder as a “hypokinetic dysarthria”; they attribute it to respiratory, phonatory, and articulatory dysfunction. The consumption of a meal takes an inordinately long time. Each morsel of food must be swallowed before the next bite is taken. Walking becomes reduced to a shuffle; the patient frequently loses his balance, and in walking forward or backward must “chase the body's center of gravity” with a series of short steps in order to avoid falling (festination). Defense and righting reactions are faulty. Falls do occur, but surprisingly infrequently given the degree of postural instability. Gait is typically improved by sensory guidance, as by holding the patient at the elbow, whereas obstacles have the opposite effect, at times causing the patient to “freeze” in place. Difficulty in turning over in bed is a characteristic feature as the illness advances, but the patient rarely volunteers this information.

Shaving or applying lipstick becomes difficult, as the facial muscles become more immobile and rigid.

Persistent extension or clawing of the toes, jaw clenching, and other fragments of dystonia may enter the picture but rarely are early findings.

As noted above, these various motor impediments and tremor characteristically begin in one limb (more often the left) and spread to one side and later to both sides, until the patient is quite helpless. Yet in the excitement of some unusual circumstance (a fire, for example), the patient is capable of brief but remarkably effective movement (*kinesis paradoxica*).

Regarding other elicitable neurologic signs, there is an inability to inhibit blinking in response to a tap over the bridge of the nose or glabella (Myerson sign), but grasp and suck reflexes are not present and buccal and jaw jerks are rarely enhanced. Commonly there is an impairment of upward gaze and convergence; if noted early in the disease, this raises the possibility of progressive supranuclear palsy. The bradykinesia may extend to eye movements, in that patients may show a delay in the initiation of gaze to one side, slowing of conjugate movements (decreased maximal saccadic velocity), hypometric saccades, and breakdown of pursuit movements into small saccades. There are no sensory changes. Drooling is troublesome; an excess flow of saliva has been assumed, but actually the problem is one of failure to swallow with normal frequency. Seborrhea and excessive sweating are probably secondary as well, the former due to failure to cleanse the face sufficiently, the latter to the effects of the constant motor activity. Postural instability can be elicited by tugging at the patient's shoulders from behind and noting the lack of a small step backward to maintain balance. The tendon reflexes vary, as they do in normal individuals, from being barely elicitable to brisk. Even when parkinsonian symptoms are confined to one side of the body, the reflexes are usually equal on the two sides, and the plantar responses are flexor. Exceptionally, the reflexes on the affected side are slightly more brisk, which raises the question of corticospinal involvement; but the plantar reflex remains flexor. In these respects, the clinical picture differs from that of corticobasal ganglionic degeneration, in which rigidity, hyperactive tendon reflexes, and Babinski signs are combined with apraxia (see further on). There is a tendency to syncope in some cases; this was found by Rajput and Rozdilsky to be related to cell loss in the sympathetic ganglia. However, syncope is never as prominent as in striatonigral degeneration.

At times, Parkinson disease is complicated by a dementia, a feature that had been commented upon by Charcot. The reported frequency of this combination varies considerably, based on the selection of patients and type of testing. An estimate of 10 to 15 percent ([Mayeux et al](#)) is generally accepted and matches our experience. The incidence increases with advancing age, approaching 65 percent in Parkinson patients above 80 years of age. In some instances of Parkinson disease with dementia, MRI reveals lesions in the cerebral white matter (in T1-weighted images) not seen in parkinsonians without dementia. The pathologic basis of the dementia in Parkinson disease is discussed below.

The overall course of the disease is quite variable. In the majority of patients, the mean period of time from inception of the disease to a chairbound state is 7.5 years ([Hoehn and Yahr](#); [Martilla and Rinne](#)). On the other hand, as many as one-third of cases are relatively mild and remain stable for 10 years or more.

Diagnosis Early in the course of Parkinson disease, when only a slight asymmetry of stride or an ineptitude of one hand is present and tremor has yet to appear and impart the unmistakable stamp of the disease, a number of small signs already alluded to may be helpful in diagnosis. These include a reduced blink rate, the Myerson glabellar sign, a lack of arm swing, digital impedance (a tendency for rapid alternating movements to be slowed, to assume a tremor rhythm, or to be blocked altogether) and perceptible rigidity of one arm when the opposite limb is occupied in a motor task such as tracing circles in the air. Lack of a Babinski sign or of increased tendon reflexes in the affected limbs eliminates a corticospinal lesion as the cause of slowed movements, and lack of a grasp reflex helps to exclude a premotor cerebral disorder.

The main difficulty in diagnosis is to distinguish Parkinson disease from the many parkinsonian syndromes, some caused by other degenerative diseases and some by medications or toxins. Parkinson disease is far more common than any of the syndromes that resemble it. Bradykinesia and rigidity of the limbs and axial musculature are shared symptoms, but only in Parkinson disease is “resting” tremor an early sign, and it remains prominent even late in the illness.

The typical signs of Parkinson disease, when present in their entirety, impart an unmistakable clinical picture. When not all the signs are evident, there is no alternative but to re-examine the patient at several-month intervals until it is clear that Parkinson disease is present or until the signature of another degenerative process becomes evident (e.g., vertical gaze impairment in progressive supranuclear palsy; dysautonomia with fainting, bladder, or vocal cord signs in striatonigral degeneration; early and rapidly evolving dementia or psychosis in Lewy body disease, or apraxia in corticobasal ganglionic degeneration). If the patient's symptoms warrant, a beneficial response to levodopa also gives a reasonably secure although not entirely conclusive indication of the presence of Parkinson disease. The other parkinsonian syndromes are for the most part unchanged by the drug.

As pointed out on page 813, the epidemic of encephalitis lethargica (von Economo encephalitis) that spread over western Europe and the United States after the First World War left great numbers of parkinsonian cases in its wake. No definite instance of this form of encephalitis had been recorded before the period 1914–1918, and virtually none has been seen since 1930; hence postencephalitic parkinsonism is no longer a diagnostic consideration. Rarely, a Parkinson-like syndrome has been described with other forms of encephalitis (particularly with Japanese B virus and eastern equine encephalitis).

In England and Europe an “arteriopathic” or “arteriosclerotic” form of Parkinson disease was at one time much diagnosed, but we have never been convinced of its reality. Pseudobulbar palsy from a series of lacunar infarcts or from Binswanger disease (page 878) can cause a clinical picture simulating certain aspects of Parkinson disease, but unilateral and bilateral corticospinal tract signs, hyperactive facial reflexes, spasmodic crying and laughing, and other characteristic features distinguish spastic bulbar palsy from Parkinson disease. Of course, the parkinsonian patient in advancing years is not impervious to cerebrovascular disease, and the two conditions then overlap.

Normal-pressure hydrocephalus can create a syndrome that resembles Parkinson disease, particularly in regard to gait and postural instability and at times to bradykinesia; but rigid postures, slowness of alternating movements, hypokinetic ballistic movements, and resting tremor are not part of the clinical picture.

Senile (familial or essential) tremor is distinguished by its fine, quick quality, its tendency to become manifest during volitional movement and to disappear when the limb is in a position of repose, and the lack of associated slowness of movement, flexed postures, etc. The head is more often involved in senile tremor than in Parkinson disease. Some of the slower, alternating forms of essential tremor are difficult to distinguish from parkinsonian tremor, and one can only wait to see whether it is the first manifestation of Parkinson disease.

Progressive supranuclear palsy (see further on) is characterized by rigidity and dystonic postures of the neck and shoulders, a staring and immobile countenance, and a tendency to topple when walking—all of which are suggestive of Parkinson disease. Inability to produce vertical saccades and, later, paralysis of upward and downward gaze and eventually of lateral gaze with retention of reflex eye movements establish the diagnosis in most cases. Strict adherence to the diagnostic criteria for Parkinson disease also permits its differentiation from corticostriatospinal, striatonigral, and corticobasal ganglionic degeneration and Machado-Joseph disease—all of which are discussed in other parts of this chapter.

Paucity of movement, unchanging attitudes and postural sets, and a slightly stiff and unbalanced gait may be observed in patients with an anergic or hypokinetic (“retarded”) type of depression. Since as many as 25 to 30 percent of parkinsonian patients are depressed, the separation of these two conditions may then be difficult (see page 1612). The authors have seen patients who were called parkinsonian by competent neurologists but whose movements became normal when antidepressant medication or electroconvulsive therapy was given.

The rapid onset of the Parkinson syndrome, especially in conjunction with other medical diseases, should always raise the suspicion of drug effects; phenothiazines, haloperidol, and the neuroleptics pimozide and metoclopramide, used at times as antiemetics, all cause a slight masking of the face, stiffness of the trunk and limbs, lack of arm swing, fine tremor of the hands, and mumbling speech. They may also evoke an inner restlessness, a “muscular impatience,” an inability to sit still, and a compulsion to move about much like that which occurs at times in the parkinsonian patient (akathisia; page 118). Spasms of the neck, face, and jaw muscles (open mouth, protruded tongue, retrocollis or torticollis, grimacing) may also be provoked by such drugs. A mild, localized rigidity of an arm due to local tetanus was studied by R. D. Adams) in a patient who had been referred as a case of acute parkinsonism.

All in all, if one adheres to the strict definition of Parkinson disease—bradykinesia, “resting” tremor, postural changes and instability, cogwheel rigidity, and response to L-dopa—errors in diagnosis are few. Yet in a series of 100 cases, studied clinically and pathologically by Hughes and associates, the diagnosis was inaccurate in 25 percent. The reasons are that about this number of Parkinson patients do not have the characteristic tremor and about 10 percent do not respond to L-dopa. These authors noted that early dementia and autonomic disorder and the presence of ataxia and corticospinal signs were reliable exclusion criteria.

Pathology and Pathogenesis It is now accepted that a loss of pigmented cells in the substantia nigra and other pigmented nuclei (locus ceruleus, dorsal motor nucleus of the vagus) is the most constant finding in both idiopathic and postencephalitic Parkinson disease. The substantia nigra is visibly pale to the naked eye; microscopically, the pigmented nuclei show a marked depletion of cells and replacement gliosis, findings that enable one to state with confidence that the patient must have suffered from Parkinson disease. Also, many of the remaining cells of the pigmented nuclei contain eosinophilic cytoplasmic inclusions with a faint halo, called Lewy bodies. These are seen in practically all cases of idiopathic Parkinson disease. They were present in a few postencephalitic cases as well, but in the latter neurofibrillary tangles were more usual. However, both of these cellular abnormalities appear occasionally in the substantia nigra of aging, nonparkinsonian individuals. Possibly the individuals with Lewy bodies would have developed Parkinson disease if they had lived a few more years. Noteworthy is the finding by McGeer et al that nigral cells normally diminish with age, from a maximal complement of about 425,000 to 200,000 at age 80. Tyrosine-hydroxylase, the rate-limiting enzyme for dopamine, diminishes correspondingly. These authors found that in patients with Parkinson disease, the number of pigmented neurons was reduced to about 30 percent of that in age-matched controls. Using more refined counting techniques, Pakkenberg and coworkers estimated the average total number of pigmented neurons to be 550,000 and to be reduced by 66 percent in Parkinson patients. The number of nonpigmented neurons in their control subjects was 260,000 and again was reduced in patients by 24 percent. Thus, aging contributes importantly to nigral cell loss, but the cell depletion is so much more marked in Parkinson disease that some factor other than aging must also be operative.

Other depletions of cells are widespread, but they have not been quantitatively evaluated and their significance is less clear. There is neuronal loss in the mesencephalic reticular formation, near the substantia nigra. These cells project to the thalamus and limbic lobes. In the sympathetic ganglia, there is slight neuronal loss and Lewy bodies are seen; this is also true of the pigmented nuclei of the lower brainstem as well as of the putamen, caudatum, pallidum, and substantia innominata. Dopaminergic neurons that project to cortical and limbic structures, to caudate nucleus and nucleus accumbens, and to periaqueductal gray matter and spinal cord are affected little or not at all. The lack of a consistent lesion in either the striatum or the pallidum is noteworthy in view of the reciprocal connections between the striatum and the substantia nigra and the depletion of striatal dopamine that characterizes the parkinsonian state.

The statistical data relating Parkinson and Alzheimer diseases are difficult to assess because of different methods of examination from one reported series to another ([Quinn et al](#)). Nevertheless, the overlap of the two diseases is more than fortuitous, as indicated in an earlier part of this chapter. In our own pathologic material, the majority of the demented Parkinson patients showed Alzheimer-type changes, but there were several in whom few plaques or neurofibrillary changes could be found or in whom the cortical neuronal loss was accompanied by a widespread distribution of Lewy bodies (Lewy body dementia, discussed earlier, on page 1120).

Of great interest in recent years has been the observation, both in human opiate addicts and in monkeys, that a neurotoxin (known as MPTP) can produce irreversible signs of parkinsonism and selective destruction of cells in the substantia nigra (as described on page 105). The toxin, ingested by persons who self-administered an analogue of meperidine, was shown to bind with high affinity to an extraneural enzyme, monoamine oxidase, which transformed it to a toxic metabolite, pyridinium MPP⁺. The latter is bound by the melanin in the dopaminergic nigral neurons in sufficient concentration to destroy the cells. The precise mechanism by which MPTP produces the Parkinson syndrome is unsettled. One hypothesis is that the inner segment of the globus pallidus is rendered hyperactive because of reduction of the GABA influence of the subthalamic nucleus. The theory of an environmental toxin as a cause of Parkinson disease has been greatly stimulated by the MPTP findings. ([Uhl et al](#); see also the review by [Snyder and D'Amato](#)). The disease is more frequent in industrialized countries and agrarian areas in which toxins are commonly used, but its universal occurrence would militate against any one toxin. To date, no chemical toxin, heavy metal, etc., has been incriminated in the causation of Parkinson disease.

Provocative recent discoveries have involved the synaptic protein alpha-synuclein, the main component of Lewy bodies in both the sporadic and inherited forms of Parkinson disease as well as in Lewy body disease. Synuclein normally exists in a soluble unfolded form, but in high concentrations it forms aggregates of neurofilaments to form the Lewy body. Immunostaining techniques have also disclosed less specific proteins, such as ubiquitin and tau, within the Lewy bodies. Furthermore, as noted earlier, in four unrelated families with the rare autosomal dominant form of Parkinson disease, a mutation on chromosome 4 has been found that codes for an aberrant form of synuclein ([Polymeropoulos et al](#)). However, no gene error relating to synuclein has been found in patients with sporadic Parkinson disease and the misfolding of synuclein as a cause of the common sporadic disease is only a speculation.

Treatment Although there is no known treatment that will halt or reverse the neuronal degeneration that presumably underlies Parkinson disease, methods are now available that afford considerable relief from symptoms. Treatment can be medical or surgical, although reliance is placed mainly on drugs, particularly on L-dopa.

At present, L-dihydroxyphenylalanine (L-dopa) is unquestionably the most effective agent for the treatment of Parkinson disease, and the therapeutic results, even in those with far-advanced disease, are much better than have been obtained with other drugs, even newer ones that act as dopamine agonists. As mentioned earlier, some degree of response is so nearly universal that many neurologists use it as a diagnostic criterion. The theoretical basis for the use of this compound rests on the observation that striatal dopamine is depleted in patients with Parkinson disease but that the remaining nigral cells are capable of producing dopamine by taking up its precursor, L-dopa. The neurons of the striatum that are targets of nigral projections are not depleted and remain receptive to any dopamine released by nigral cells. Over time, however, the number of remaining nigral neurons that convert L-dopa to dopamine becomes inadequate and the receptivity to dopamine of the striatal target neurons becomes excessive, possibly as a result of denervation hypersensitivity; this results in both a reduced response to L-dopa and to paradoxical and excessive movements (dyskinesias) with each dose.

By combining a decarboxylase inhibitor (carbidopa or benserizide), which is unable to penetrate the central nervous system (CNS), with L-dopa, the decarboxylation of L-dopa to dopamine is greatly diminished in peripheral tissues. This permits a greater proportion of L-dopa to reach nigral neurons and, at the same time, a reduction in the peripheral side effects of L-dopa and dopamine (nausea, hypotension, etc.). Combinations of levodopa-carbidopa are available in a 10:1 or 4:1 ratio and the benserizide combination in a 4:1 ratio. The initial dose of levodopa-carbidopa is typically one-half of a 100-mg/25-mg tablet given two or three times daily and increased slowly until optimum improvement is achieved, usually up to a maximum of two tablets administered four times daily, or a similar dose of the 250-mg/25-mg combination. A newer class of catechol-O-methyltransferase (COMT) inhibitors, typified by tolcapone, extends the plasma half-life and the duration of L-dopa effect by preventing its breakdown (as opposed to increasing its bioavailability as with carbidopa). But these drugs require further study, for there have been several complications and rare unexplained deaths after their use.

Long-acting preparations of levodopa-carbidopa may reduce dyskinesias in some patients ([Hutton and Morris](#)) in the advanced stages of disease, but our experience with these drugs given earlier in the course has been less impressive. In transferring a patient from conventional L-dopa/carbidopa preparations to the long-acting formulation, the frequency of administration can be roughly halved while the total amount of L-dopa initially remains unchanged. The absorption of the long-acting drug, however, is approximately 70 percent, often necessitating a slight increase in total dose. To facilitate the treatment of morning rigidity and tremor, the long-acting tablet can be broken in half to speed absorption or a small dose of conventional medication can be given at the same time. Often some degree of dyskinesia must be accepted as the price to be paid for the therapeutic effect.

Bromocriptine, *pergolide*, and *lisuride* are synthetic ergot derivatives whose action in Parkinson disease is explained by their direct stimulating effect on dopamine (D₂) receptors, which are located on corticostriate neurons, thus bypassing the depleted nigral neurons. The newer nonergot dopamine agonists *ropinirole* and *pramipexole* seem to be tolerated well and have a duration of effectiveness similar to that of other D₂ agonists; these agents are very helpful in supplementing L-dopa and are now increasingly popular as the sole therapeutic agent before L-dopa is instituted. Rascol and colleagues have reported that the use of ropinirole during the first 5 years of the parkinsonian illness controlled the symptoms satisfactorily and, in addition, reduced the incidence of dyskinesias, compared to treatment with L-dopa. Why dyskinesias are less frequent with ropinirole than with L-dopa is not known. Bromocriptine should be introduced cautiously, 7.5 to 10 mg daily in three to four divided doses, and the dosage increased very slowly to an optimal level of 40 to 60 mg daily; levodopa-carbidopa should be reduced concomitantly by 50 percent. A dose of 5 to 10 mg of bromocriptine has about the equivalent effect of 100/25 mg levodopa/carbidopa. It has a longer duration of action than L-dopa and causes nausea and vomiting less often, but otherwise the action and side effects of the two drugs are much the same. Even small doses of these drugs, when first introduced, may induce a prolonged episode of hypotension. Our observations are in agreement with those of Marsden, who found that of 263 patients, all but 82 had abandoned one of the ergot dopamine agonists after 6 months because of lack of effect or adverse reactions. Nevertheless, a proportion of patients continue to benefit for up to 3 years. Ropinirole and pramipexole are useful in smoothing the effects of L-dopa and allowing a reduction in its dose. As with the ergot-based dopamine agonists, they can be utilized in some patients as the sole treatment for a limited time. They may produce sudden and unpredictable sleepiness, similar to narcolepsy, and patients should be warned of this possibility in relation to driving. More data are required to judge the efficacy of initiating therapy with a dopamine agonist rather than with L-dopa combinations.

Because of the side effects of levodopa and of dopaminergic agents, particularly in older patients, some neurologists avoid all types of pharmacotherapy if the patient is in the early phase of the disease and the parkinsonian symptoms are not troublesome. When the symptoms become more annoying, initial therapy with either amantadine 100 mg bid or an anticholinergic medication may be advised. Only when the symptoms begin to interfere with work and social life or falling becomes a threat is a carbidopa/levodopa preparation introduced, and then at the lowest possible dose—10/100 mg bid or tid. This dose is slowly increased until maximal benefit

is achieved.

Another approach, now controversial, has been to initiate the treatment of new cases of Parkinson disease with the monoamine oxidase inhibitor selegiline, 5 mg bid, and to continue its use until symptoms become disabling, at which point L-dopa or a dopamine agonist is introduced. Selegiline inhibits the intracerebral metabolic degradation of dopamine, and clinical trials conducted by the Parkinson Study Group have suggested that it slows progression of the disease in its early stages. Subsequent observations, however, have not confirmed the view that selegiline markedly alters the natural course of the disease, and we use it infrequently.

As already mentioned, L-dopa is not without significant side effects, so that its use is limited in some circumstances. Approximately two-thirds of patients tolerate the drug initially and experience few serious adverse effects; one-third will show dramatic improvement, especially in hypokinesia and tremor. Many patients are at first troubled by nausea, especially if the medication is not taken with meals, and a few have orthostatic hypotensive episodes. Nausea usually disappears after several weeks of continued use or can be allayed by the specific dopaminergic chemoreceptor antagonist domperidone. Coincident psychiatric symptoms may also present problems and are to be expected in 15 to 25 percent of patients, particularly in the elderly. Depression is occasionally a serious problem, even to the point of suicide; delusional thinking may occur in these circumstances. This combination of movement and psychiatric disorders is difficult to treat, and one must institute an antidepressant regimen or one of the newer class of antipsychotic medications that are associated with few extrapyramidal side effects, as described below and in [Chap. 50](#). Trazodone has been helpful in treating depression and insomnia, which may be a major problem. The selective serotonin reuptake inhibitors are useful in apathetic depressions, but some patients report worsening of parkinsonian symptoms. Excitement and aggressiveness appear in a few. A return of libido may lead to sexual assertiveness.

Confusion and outright *psychosis* (hallucinations and delusions), seen in advanced cases of Parkinson disease when high doses of L-dopa are required, is first treated by attempting to reduce the dose of the drug. If this is not possible, the atypical neuroleptics olanzapine, clozapine, risperidone, or quetiapine in low doses are often successful ([Friedman and Lannon](#)). The side effects of these drugs include sleepiness, orthostatic hypotension, sialorrhea, and the most serious, agranulocytosis, requiring regular monitoring of the blood count. Clozapine has been said to provide an additional benefit of suppressing dyskinesias in advanced Parkinson disease ([Bennett et al](#)), but it requires weekly surveillance of the blood count because of the idiosyncratic occurrence of agranulocytosis in up to 2 percent of patients. Although useful in the treatment of frankly psychotic patients, these drugs tend to be far less effective once dementia has supervened. The anticonvulsant valproate is also said to be useful in this circumstance, but our experience with this drug has not been as favorable as with clozapine. Despite their lesser tendency to produce rigidity, olanzapine and probably the other similar agents in high doses eventually worsen motor disability.

The most common and troublesome effects of L-dopa, requiring individualization of therapy, are end-of-dose failure, the “on-off” phenomenon, and the induction of involuntary movements—restlessness, head wagging, grimacing, lingual-labial dyskinesia, and choreoathetosis and dystonia of the limbs, neck, and trunk. *The on-off phenomenon* refers to an unpredictable change in the patient, in a matter of minutes or from one hour to the next, from a state of relative mobility to one of complete or nearly complete immobility. These disorders eventually appear in about 75 percent of patients within 5 years. Above a certain daily dose, which varies from patient to patient, very few patients escape these effects, forcing a reduction in dosage.

If involuntary movements are induced by relatively small doses of L-dopa, the therapeutic effect may be enhanced to some extent by the addition of other dopaminergic agents, such as pergolide, bromocriptine, or the newer nonergot preparations, such as ropinirole and pramipexole (see below) and, to some extent, amantadine. The use of long-acting preparations of L-dopa may also be helpful in reducing dyskinesias, as mentioned above. *Amantadine*, an antiviral agent, is thought to act by releasing dopamine from striatal neurons; it also has an anticholinergic property. It is given in doses of 50 to 100 mg three times daily. Its benefit appears almost immediately but tends to be slight. In addition to anticholinergic symptoms (dry mouth, etc.), the side effects are similar to those of L-dopa but are much milder. Edema of the legs has been troublesome in some patients. However, amantadine is effective in combination with L-dopa and may reduce the dyskinesias and motor fluctuations associated with advanced disease ([Verhagen Metman et al](#)). Given alone or in combination with L-dopa, it offers a modest alternative treatment for patients with early Parkinson disease or those who are having untoward effects with standard doses of L-dopa.

The notion that the administration of L-dopa early in the disease might reduce the period over which it remains effective has been largely dispelled, but some experts continue to adhere to this idea. Cedarbaum et al, who reviewed the course of the illness in 307 patients over a 7-year period, found no evidence that the early initiation of L-dopa treatment predisposes to the development of motor response fluctuations, dyskinesia, and dementia. Also, the large multicenter study reported by Diamond et al indicated that patients who were given L-dopa early in the disease actually survived longer and with less disability than those who were started late.

Anticholinergic agents have long been in use and are still given occasionally, either in conjunction with L-dopa or to patients who cannot tolerate the latter drug. Several synthetic preparations are available, the most widely used being trihexyphenidyl (Artane) and benzotropine mesylate (Cogentin) and amantadine (see above). When tremor is the most prominent symptom, we have had success with the related drug ethopropazine (Parsidol, Parsitan in Canada). In order to obtain maximum benefit from the use of these drugs, they should be given in gradually increasing dosage to the point where toxic effects appear: dryness of the mouth (which can be beneficial when drooling of saliva is a problem), blurring of vision from pupillary mydriasis (for which corrective glasses may be indicated), constipation, and sometimes urinary retention (especially with prostatism). Unfortunately, mental slowing, confusional states, hallucinations, and impairment of memory—especially in patients with already impaired mental function—are frequent side effects of these drugs and sharply limit their usefulness. Ethopropazine, 50 to 200 mg daily, is given in divided doses. We have effectively managed cases of isolated parkinsonian tremor in young patients using anticholinergic drugs alone. The optimum dosage level is the point at which the greatest relief from tremor is achieved within the limits of tolerable side effects. Occasionally, further benefit may accrue from the addition of one of the antihistaminic drugs, such as diphenhydramine or phenindamine. An important note of warning: anticholinergic agents or L-dopa should not be discontinued abruptly in advanced cases. If this is done, the patient may become totally immobilized by a sudden and severe increase of tremor and rigidity; rarely, a neuroleptic syndrome has been induced by such withdrawal.

Long-term treatment with L-dopa or dopamine receptor agonists has not prevented the slow advance of the disease. With progressive loss of nigral cells, there is an increasing inability to store L-dopa and periods of drug effectiveness become shorter. In some instances, the patient becomes so sensitive to L-dopa that as slight an excess as 50 to 100 mg will precipitate choreoathetosis; if the dose is lowered by the same amount, the patient may develop disabling rigidity. With the end-of-dose loss of effectiveness and on-off phenomenon, which with time become increasingly frequent and unpredictable, the patient may experience pain, respiratory distress, akathisia, depression, anxiety, and even hallucinations. Some patients function quite well in the morning and much less well in the afternoon, or vice versa. In such cases, and for end-of-dose and on-off phenomena, one must titrate the dose of L-dopa and utilize more frequent doses during the 24-h day; combining it with a dopamine agonist or use of the long-acting preparations may be helpful. Sometimes temporarily withdrawing L-dopa and at the same time substituting other medications will control the on-off phenomenon.

Based on the hypothesis that alimentary-derived amino acids antagonize the clinical effects of L-dopa, the use of a low-protein diet has been advocated as a means of controlling the motor fluctuations described above ([Pincus and Barry](#)). Symptoms can often be reduced by the simple expedient of eliminating dietary protein from breakfast and lunch. Moreover, this dietary regimen may permit the patient to reduce the total daily dose of L-dopa. Such dietary manipulation is worth trying in appropriate patients; it is not harmful, and most of our patients who have persisted with this diet have reported improvement in their symptoms or an enhanced effect of L-dopa.

Surgical Measures Until recently, success with L-dopa had practically replaced the use of ablative surgical therapy. The latter involves the stereotactic placement of lesions in either the globus pallidus, ventrolateral thalamus, or subthalamic nucleus, contralateral to the side of the body chiefly affected. The best results have been obtained in relatively young patients, in whom unilateral tremor or rigidity, rather than akinesia, are the predominant symptoms. The symptoms that have responded least well to operation (or to treatment with L-dopa) are postural imbalance and instability, paroxysmal akinesia, bladder and bowel disturbances, dystonia, and speech difficulties.

In the last decade, through the work of Laitinen and others, this mode of therapy has been revived and expanded. Under precise stereotactic control and with placement of a lesion in the posterior and ventral (medial) part of the globus pallidus, improvement of contralateral parkinsonian symptoms has been effected more reliably than in the past. Also, postoperatively, there is an enhanced responsiveness to L-dopa and a reduction of drug-induced dyskinesias. To what extent the improvement will be sustained remains to be determined, since the disease process continues to advance. In patients who have been studied for more than a few years, the beneficial effects on dyskinesias contralateral to the operation are sustained to some extent, but not in the ipsilateral limbs. The improvement in “off-state” bradykinesia is lost after 2 or so years and any betterment in axial rigidity and imbalance is lost in many patients within a year of operation, as summarized by Gregory and by Lang et al. In the only randomized trial to date that has compared pallidotomy to continued medical treatment of patients with dyskinesias, bradykinesia, or severe fluctuations in response to L-dopa, de Bie and colleagues demonstrated a clear improvement in motor function after surgery, while the group treated with medication continued to worsen. Using patient diaries, they estimated that dyskinesias were reduced 50 percent contralateral to the operated side and that parkinsonian symptoms during the “off phase” were improved by 30 to 50 percent. These improvements do not persist indefinitely and are in part due to the ability to

reduce the dose of L-dopa. It should be mentioned that most groups have abandoned the pallidum as a surgical target in favor of the subthalamic nucleus.

Recently, through the use of implanted electrodes, the sites that are the targets of ablative procedures have been subjected to high-frequency stimulation—with virtually identical if not better results. In particular, high-frequency stimulation of the subthalamic nucleus has produced impressive improvement in all features of the disease ([Limousin et al](#)). Long-term studies are in progress to determine the persistence of these effects and their merits in comparison to ablative lesions.

The cerebral implantation of adrenal medullary tissue from 8- to 10-week-old human fetuses has provided a modest but undeniable improvement in motor function ([Spencer et al](#)), and some patients also appear to have benefited from the striatal implantation of human fetal and porcine nigral cells and autologous adrenal cells. These procedures are hampered by many difficulties, mainly in obtaining tissue and the failure of grafts to survive. Much of the original enthusiasm for these procedures has subsided, and it seems unlikely that they will have wide applicability in the treatment of Parkinson disease in the near future. Investigation into their possible usefulness continues.

Finally, in the management of the patient with Parkinson disease, one must not neglect the maintenance of optimum general health and neuromuscular efficiency by a planned program of exercise, activity, and rest; expert physical therapy and exercises such as those performed in yoga may be of help in achieving these ends. Sleep may be aided by the soporific antidepressants. Postural imbalance can be greatly mitigated by the use of a cane or walking frame. Hypotensive episodes respond to 0.5 mg of fludrocortisone (Florinef) each morning. In addition, the patient often needs much emotional support in dealing with the stress of the illness, in comprehending its nature, and in carrying on courageously in spite of it.

Striatonigral Degeneration and Multiple System Atrophy

Closely related to Parkinson disease clinically but with a different pathologic basis is a state designated by Adams and colleagues as *striatonigral degeneration*. The pathologic changes were found by chance in four middle-aged patients, none with a family history of similar disease, in three of whom a parkinsonian syndrome had been described clinically. In one of the three, who had been examined clinically, the typical rigidity, stiffness, and akinesia had begun on one side of the body, then spread to the other, and progressed over a 5-year period, but with little or none of the characteristic tremor of idiopathic Parkinson disease. A flexed posture of the trunk and limbs, slowness of all movements, poor balance, mumbling speech, and a tendency to faint when standing were other elements in the clinical picture. Mental function was intact, and there were no reflex changes, no suck and grasp reflexes, and no cerebellar signs or involuntary movements. The other two patients had been seen by competent neurologists who had made a diagnosis of Parkinson disease. Some of the symptoms had been partially relieved by anticholinergic drugs. There was an early-onset cerebellar ataxia in the fourth patient, later obscured by a Parkinson syndrome.

In each case the postmortem examination disclosed extensive loss of neurons in the zona compacta of the substantia nigra, but notably there were no Lewy bodies or neurofibrillary tangles in the remaining cells. Even more striking were the degenerative changes in the putamina and to a lesser extent in the caudate nuclei. These structures were greatly reduced in size and had lost most of their neurons—more of the small than the large ones and more on the side opposite the first clinical symptoms. The findings were suggestive of the striatal lesions of Huntington chorea except that the cell loss was greater in the putamen than in the caudatum. Secondary pallidal atrophy (mainly a loss of striatopallidal fibers) was present. In the fourth patient there was, in addition, an advanced olivopontocerebellar degeneration.

Following the original report, in 1964, many patients were recognized in whom the changes of striatonigral and olivopontocerebellar degeneration (page 1148) were combined and in some of whom the symptoms and signs of cerebellar ataxia actually preceded the parkinsonian manifestations. Equally frequent is a predominantly extrapyramidal syndrome accompanied by autonomic dysfunction, as described below.

Shy-Drager Syndrome Nearly half of the patients with striatonigral degeneration are handicapped by *orthostatic hypotension*, which proves at autopsy to be associated with loss of intermediolateral horn cells and pigmented nuclei of the brainstem. This combined parkinsonian and autonomic disorder, generally referred to as the Shy-Drager syndrome, has already been mentioned in the chapters on fainting and the autonomic nervous system (pages 396 and 564). In addition to orthostatic hypotension, symptoms include impotence, loss of sweating, dry mouth, miosis, and urinary retention or incontinence. Vocal cord palsy is an important and sometimes the initial manifestation of the autonomic disorder, causing dysphonia or even stridor and airway obstruction, and requiring tracheostomy (see page 565).

Multiple System Atrophy Because of the recognition that the clinical and pathologic features of sporadic striatonigral degeneration, with or without autonomic failure, and those of olivopontocerebellar atrophy often coexist, each component expressing itself variably in any individual, Graham and Oppenheimer, in 1969, proposed the term *multiple system atrophy* (MSA), which has gained wide acceptance. Several large series of cases of this complex syndrome have now been published, providing a perspective on the frequency and nature of its components.

In the Brain Tissue Bank of the Parkinson Disease Society of Great Britain, MSA accounted for 13 percent of cases that had been identified during life as idiopathic Parkinson disease. All of the patients with MSA had one or more symptoms of autonomic failure (postural hypotension, urinary urgency or retention, urinary or fecal incontinence, impotence, and dysphonia or stridor). Babinski signs were present in half of the patients and cerebellar ataxia in one-third. Tremor was rare. Males were affected more often than females.

In a series of 100 patients (67 men and 33 women) studied by Wenning and coworkers, the disease began with a striatonigral-parkinsonian syndrome in 46 percent; often it was asymmetrical to begin with. Mild tremor was detected in 29 percent, but in very few was it of the “resting” Parkinson type. In another 41 percent the illness began with autonomic manifestations; orthostatic hypotension occurred eventually in almost all patients, but it was disabling in only a few. Cerebellar features dominated the initial stages of the disease in only 5 percent, but ataxia was eventually obvious in half of the group. The illness, on the whole, was more severe than Parkinson disease, since more than 40 percent of patients were confined to a wheelchair or otherwise severely disabled within 5 years. These observations generally match the findings in a group of 188 patients described by Quinn and colleagues. In that series, parkinsonism was evident at some time in 89 percent of patients and was conjoined with cerebellar signs in half, pyramidal signs in 60 percent, and autonomic features in 77 percent. The other main presentation was with ataxia of gait, and this was accompanied by pyramidal signs in 69 percent; one-quarter of the patients had parkinsonism alone.

Colosimo and colleagues, who reviewed the clinical findings in 16 pathologically verified cases of multiple system atrophy, found that several signs—namely, the relative symmetry of the signs and rapid course, the lack of response to L-dopa and absence of tremor, and the presence of autonomic disorders—reliably distinguished this syndrome from Parkinson disease. These observations are in keeping with our own. It is noteworthy that levodopa has had little or no effect or has made these patients worse early in the disease. This is probably attributable to the loss of striatal dopamine receptors.

The diagnosis of MSA has been enhanced by imaging techniques. Both MRI and CT scans frequently show atrophy of the cerebellum and pons. The putamina are hypodense on T2-weighted MR images and may show an increased deposition of iron. Studies with PET have disclosed an impairment of glucose metabolism in the striatum and to a lesser extent in the frontal cortex—a reflection, no doubt, of the loss of functioning neuronal elements in these parts. Finally, it must be repeated that despite the frequent concurrence of striatonigral degeneration, olivopontocerebellar degeneration, and the Shy-Drager syndrome, *each of these disorders may occur in pure form*, for which reason we prefer to retain their original designations. Indeed, in a series of 51 patients with olivopontocerebellar atrophy followed by Gilman et al for up to 10 years, only 17 had acquired a parkinsonian syndrome or autonomic failure.

In recent years, attention has been drawn to the presence of argyrophilic staining material in glial cells of patients with the MSA complex and to its possible relevance in the pathogenesis of this syndrome. The abnormal staining material is most prominent in the cytoplasm of oligodendrocytes but is found in other glial cells and in neurons as well. These cytoplasmic aggregates have been referred to as “oligodendroglial cytoplasmic inclusions” ([Papp et al](#)), although morphologically they bear little resemblance to the discrete rounded inclusions that have come to be accepted as characteristic of other degenerative CNS diseases (e.g., Lewy bodies). It has been proposed that the glial accumulations of argyrophilic material represent a reliable histopathologic hallmark of sporadic cases of MSA ([Chin and Goldman; Lantos](#)). These aggregates, however, are far from specific; they have been identified in practically every degenerative disease that has been subjected to sensitive silver impregnation stains (Gallyas silver technique). Moreover, appropriate control studies to determine whether the argyrophilic glial inclusions are found in *nondegenerative* lesions in brain (at the edge of an infarct, for example) are lacking. Another serious deficiency is the lack of any systematic information about the argyrophilic staining properties of glia in relation to the aging brain. The fundamental question remains unanswered: Do the cytoplasmic glial aggregates play a central role in the genesis of the degenerative diseases, or are they simply some form of detritus that accumulates in glia as a reaction to or a by-product of the basic abnormality—namely, the wasting and loss of neurons?

Progressive Supranuclear Palsy

In 1963 Richardson, Steele, and Olszewski crystallized medical thought about a clinicopathologic entity—progressive supranuclear palsy, or PSP—to which there had been only ambiguous reference in the past. The condition is not rare or unusual. By 1972, when Steele reviewed the subject, 73 cases (22 with postmortem examinations) had been described in the medical literature, and several examples are to be found in every large neurologic center; the present authors encounter approximately five new cases yearly, most of them not previously diagnosed. Rare familial clusters have been described in which the pattern of inheritance is compatible with autosomal dominant transmission ([Brown et al](#); [de Yébenes et al](#)). No toxic, encephalitic, racial, or geographic factor has been incriminated as a possible cause.

Clinical Features Characteristically the disease has its onset in the sixth decade (range 45 to 75 years) with some combination of difficulty in balance, abrupt falls, visual and ocular disturbances, slurred speech, dysphagia, and vague changes in personality, sometimes with an apprehensiveness and fretfulness suggestive of an agitated depression. The commonest early complaint is unsteadiness of gait and unexplained falling. At first the neurologic and ophthalmologic examinations may be unrevealing, and it may take a year or longer for the characteristic syndrome—comprising supranuclear ophthalmoplegia, pseudobulbar palsy, and axial dystonia—to develop fully.

Difficulty in voluntary vertical movement of the eyes, often downward but sometimes upward and involving voluntary saccades first, is a characteristic and relatively early feature in more than half of the cases. A related but more subtle sign has been the finding of hypometric saccades in response to an optokinetic drum or striped cloth moving vertically in one direction (usually best seen with stripes moving downward) compared to the saccades with the targets moving in the opposite direction or horizontally. Later, both the ocular pursuit and refixation movements deteriorate and eventually all voluntary eye movements are lost, first the vertical ones and then the horizontal ones as well. However, if the eyes are fixated on a target and the head is turned, full movements can be obtained, proving the supranuclear, nonparalytic character of the gaze disorder. Other prominent oculomotor signs are sudden jerks of the eyes during fixation, cogwheel pursuit movements, and hypometric saccades of long duration ([Troost and Daroff](#)). Bell's phenomenon (reflexive upturning of eyes on forced closure of the eyelids) and ability to converge are also lost, and the pupils then become small. The upper eyelids may be retracted, and the wide-eyed, unblinking stare, imparting an expression of perpetual surprise, is highly characteristic. Blepharospasm and involuntary eye closure are prominent in some cases. In the late stages, the eyes may be fixed centrally, and all oculocephalic and vestibular reflexes may be lost as well. It should be emphasized, however, that *a proportion of patients do not demonstrate these eye signs for a year or more* after the onset of the illness.

The *gait disturbance* and *repeated falling* have proved difficult to analyze. Walking becomes more and more awkward and tentative; the patient has a tendency to totter and fall repeatedly but has no ataxia of the limbs or Romberg sign. Some patients tend to lean and fall backward (retropulsion). One of our patients, a large man, fell repeatedly, wrecking household furniture as he went down, yet careful examination provided no clue as to the basic defect in this “toppling phenomenon.”

Along with the oculomotor and balance disorders, there is a gradual stiffening and extension of the neck (in one of our cases it was sharply flexed), but this is not an invariable finding. The face acquires a staring, “worried” expression with a furrowed brow and staring demeanor, made more striking by the paucity of eye movements. A number of our patients have displayed mild dystonic postures of a hand or foot, especially as the illness advanced but occasionally early on. The limbs may be slightly stiff, with Babinski signs in a few cases.

The stiffness, slowness of movement, difficulty in turning and sitting down, and hypomimia may suggest a diagnosis of Parkinson disease. However, the facial expression of the PSP patient is more a matter of tonic grimace than of lack of movement, and the lack of tremor, erect rather than stooped posture, and prominence of oculomotor abnormalities also serve to distinguish the two disorders. The signs of pseudobulbar palsy are eventually prominent. The face becomes less expressive (“masked”), speech is slurred, the mouth tends to be held open, and swallowing is difficult. Forced laughing and crying, said to be infrequent, have been present in about half of our cases. Many patients complain of sleep disturbances. The total sleep time and rapid-eye-movement (REM) sleep are reduced, and spontaneous awakenings during the night are more frequent and longer than in normal individuals of the same age. Features such as focal limb dystonia, palilalia, myoclonus, chorea, orofacial dyskinesias, and disturbances of vestibular function are observed in some cases. Finally the patient becomes anarthric, immobile, and quite helpless. Some patients do eventually become forgetful and appear apathetic and slow in thinking; a few are irritable and at times euphoric. Complaints of urinary frequency and urgency are very frequent in advanced cases. Dementia of some degree is probably present in many cases but is mild in most.

By MRI, one can, in advanced cases, visualize the atrophy of the mesencephalon (superior colliculi, red nuclei) giving rise to a “mouse ears” configuration. The CSF remains normal.

Although most cases of PSP are sporadic, the disease can be familial. Rojo and coworkers have described 12 pathologically confirmed pedigrees. The mode of inheritance is thought to be autosomal dominant with incomplete penetrance. The authors made note of the variable phenotypical expression of the disease even within a single pedigree.

Postmortem examinations have disclosed a bilateral loss of neurons and gliosis in the periaqueductal gray matter, superior colliculus, subthalamic nucleus of Luys, red nucleus, pallidum, dentate nucleus, and pretectal and vestibular nuclei, and to some extent in the oculomotor nucleus. The neurons of the cerebral cortex have been involved in some cases (shown by staining of tau protein), but these changes apparently do not correlate with dementia. The cerebellar cortex is usually spared. Loss of the medullated fiber bundles arising from these nuclear structures has been observed. A remarkable finding has been the neurofibrillary degeneration of many of the residual neurons. The neurofibrillary tangles are thick and often composed of single strands, either twisted or in parallel arrangement. We have followed several patients who had no disorder of eye movement during life but in whom the typical pathologic changes of PSP were found unexpectedly. In one such case there was a subcortical type of dementia, and in another, focal limb dystonia and parkinsonism.

The cause and nature of this disease are quite obscure. Attempts to transmit it to primates by the inoculation of fresh brain tissue have failed. Conceivably, some cases originally considered to be instances of postencephalitic parkinsonism were examples of PSP. Studies with PET have demonstrated a decrease in blood flow—most marked in the frontal lobes—and a lesser extent of oxygen utilization in central structures ([Leenders et al](#)). Striatal dopamine formation and storage have been significantly decreased compared with control values.

Progressive supranuclear palsy should be suspected whenever an older adult inexplicably develops a state of imbalance, frequent falls with preserved consciousness, and variable extrapyramidal symptoms, particularly dystonia of the neck, ocular palsies, or a picture resembling pseudobulbar palsy. When only a parkinsonian syndrome without tremor is present, the main diagnostic consideration is striatonigral degeneration or the cortical-basal-ganglionic syndrome, described below.

L-Dopa has been of slight but unsustained benefit in some of our patients, and combinations of L-dopa and anticholinergic drugs have been entirely ineffective in others. A marked response to these drugs should, of course, suggest the diagnosis of Parkinson disease. Recently, the drug zolpidem, a GABAergic agonist of benzodiazepine receptors, has been reported to ameliorate the akinesia and rigidity of PSP ([Daniele et al](#)); however, these observations require corroboration.

Cortical-Basal-Ganglionic Syndromes

Over the years, the authors have observed several elderly patients, both men and women, in whom the essential abnormality was a progressive extrapyramidal rigidity, combined with signs of corticospinal disease. Sometimes a mild postural action tremor (beginning unilaterally and suggestive in some respects of Parkinson disease) was added. The relation of such cases to corticostriatospinal degeneration, described earlier, is indeterminate. The patients, though able to exert considerable muscle power, cannot effectively direct their voluntary actions. Attempts to move a limb to accomplish some purposeful act might result in a totally inappropriate movement, always with great enhancement of rigidity in the limb and in other affected parts, or the limb may drift off and assume an odd posture, such as a persistent elevation of the arm without the patient's awareness—a kind of involuntary catalepsy. The disorder of limb function has some of the attributes of an apraxia, but the hand postures, involuntary movements, and changes in tone are at times more reminiscent of what has been described as “the alien hand.” Some patients exhibit an anosognosia.

With progression of the disease, the limbs—first on one side, then on both sides of the body—and the cranial muscles become involved; apraxia and variable combinations of rigidity, bradykinesia, hemiparesis, sensory ataxia, and postural and action tremor and sometimes myoclonic jerking finally render the patient helpless—unable to sit, stand, speak, or take care of his basic needs. Apraxias of gaze, eyelid opening and closure, and stimulus-sensitive myoclonus appear in some cases. Mental deterioration occurs late and only in some cases. In a few cases, there is some involvement of lower motor neurons with resulting amyotrophy. The condition progresses for 5 years or more before some medical complication overtakes the patient. Wenning and colleagues have described a series of 14 such patients in whom the diagnosis was confirmed at postmortem examination. The most common early symptom was an asymmetrical clumsiness of the limbs, in half of

the patients with rigidity and in one-fifth with tremor; as the illness progressed, almost all the patients developed an asymmetrical or unilateral akinetic-rigid syndrome, various forms of gait disorder, and dysarthria. Stimulus-induced myoclonus and pyramidal signs, mentioned in other reports, were not prominent, and fewer than half the patients exhibited an alien-hand phenomenon; limitations of vertical gaze and frontal lobe release signs eventually became apparent in half of the patients.

Postmortem examination of several of our cases, reported by Rebeiz and colleagues, has disclosed a combination of findings that stamps the disease process as unique. Cortical atrophy (mainly in the frontal motor-premotor and anterior parietal lobes) is associated with degeneration of the substantia nigra and, in one instance, of the dentatorubrothalamic fibers. The loss of nerve cells is fairly marked, but there is no gross lobar atrophy, as occurs in Pick disease. The neuronal degeneration may be more on one side than the other. There is moderate gliosis in the cortex and underlying white matter. Many of the residual nerve cells are swollen and chromatolyzed with eccentric nuclei, a state that was called *achromasia* by Rebeiz and colleagues; it resembles the central chromatolysis of axonal reaction. More recently, the affected neurons and adjacent glia have been shown to be filled with tau protein, but no Pick bodies, Alzheimer fibrillary changes, senile plaques, granulovacuolar changes, amyloid deposits, or Lewy bodies are seen. Both CT and MRI have demonstrated asymmetrical cerebral and pontine atrophy, and PET studies have shown thalamoparietal metabolic asymmetries—a greater reduction of glucose metabolism on the side of the most extensive lesion ([Riley et al](#)).

Many investigators have searched unsuccessfully for clues as to the cause and pathogenesis of this disease. There is no family history. No organ other than the CNS is affected. The progression is relentless. None of the drugs in common use for spasticity, rigidity, and tremor has been helpful. We know of no attempt to transfer the disease to primates.

Marinescu has described a rather different state resembling more a severe form of Alzheimer disease, but with signs of both pyramidal and extrapyramidal disease (rigidity, tremor, nystagmus, incoordination, confusion, disorientation, and loss of memory). There was amyloidosis of blood vessels (so-called Scholz's perivascular plaques) in the cerebral white matter as well as in the liver and kidney. The disease bears some resemblance to the corticostriatospinal degeneration ("spastic pseudosclerosis") of Jakob discussed on page 1126. The relation of this disease to the corticopallidospinal and the pallidopyramidal syndromes first described by Davison (1932, 1954) is also uncertain. The features of eight such cases ("pallido-pyramidal" syndrome) have more recently been summarized by Tranchant and associates.

Dystonic Disorders

Dystonia Musculorum Deformans (Torsion Dystonia) Dystonia as a symptom has been discussed on pages 79 and 112. Here we are concerned with a disease or diseases of which dystonia is the major manifestation. Schwalbe's account, in 1908, of three siblings of a Jewish family who were afflicted with progressive involuntary movements of trunk and limbs probably represents the first description of the disease. In 1911, Oppenheim contributed other cases and coined the term *dystonia musculorum deformans* in the mistaken belief that the disorder was primarily one of muscle and always associated with deformity. Flatau and Sterling, in the same year, first suggested that the disease might have a hereditary basis and gave it the more accurate name *torsion dystonia of childhood*. At first thought to be a manifestation of hysteria, it gradually came to be established as a morbid entity with a preference for Russian and Polish Jews. Soon thereafter, a second hereditary form of torsion dystonia, affecting non-Jews, was defined. The epidemiologic study of Eldridge, who analyzed all reported primary cases up to 1970, revealed two patterns of inheritance, one autosomal recessive, the other dominant. The recessive form begins in early childhood, is progressive over a few years, and is restricted to Jewish patients with normal and often even superior intelligence. The dominant form begins later, usually in late childhood and adolescence, progresses more slowly, and is not limited to any ethnic group.

With widening clinical experience, the spectrum of dystonic syndromes has been greatly expanded to include an array of hereditary and nonhereditary forms, both generalized and restricted, as well as symptomatic (secondary) types due to vascular, metabolic (Wilson and Hallervorden-Spatz disease), and other degenerative forms (Huntington chorea among many others.)

As indicated in [Chap. 6](#), most instances of idiopathic (primary) dystonias that come to our attention, particularly the segmental or restricted types, do not conform to the classic hereditary types as defined above. In general, these more restricted types have a later onset and a relatively milder, more slowly progressive course, with a tendency to involve the axial or the distal musculature alone; only the paravertebral, cervical, or cranial muscles may be involved (focal dystonia including torticollis and writer's cramp), with little change from year to year. The clinical classification of the predominantly adult-onset dystonias is made more complex by the fact that both the restricted and generalized forms may be sporadic or familial in type. Bressman et al, for example, have described a restricted (cervicocranial) adult-onset form of dystonia in four generations of a non-Jewish family. The symptomatology included cervical dystonia, facial grimacing, dysarthria, and dysphonia. In one of our familial cases, a dystonia of the foot appeared during adolescence and later disappeared; we have also observed this to happen in spasmodic torticollis, which is another form of restricted or segmental dystonia, described further on.

In a survey of idiopathic torsion dystonia in the United Kingdom by Fletcher and associates, both generalized and restricted varieties were included. The investigators concluded that approximately 85 percent of these cases were due to an autosomal dominant gene of low penetrance and that a small proportion represented new mutations. They could not confirm the existence of autosomal recessive or X-linked patterns of inheritance in their patients. The risk of the disease in a first-degree relative of a familial case is about 25 percent.

Molecular genetic studies, though still incomplete, hold the promise of clarifying the classification of the heritable dystonias (see [Korf](#)). An abnormal gene (DYT1), which codes for the protein torsin A, has been mapped to the long arm of chromosome 9q in both Jewish and non-Jewish families and is inherited in an autosomal dominant pattern. This gene probably accounts for the majority of inherited cases of generalized dystonia. Although the penetrance of the clinical trait in these families is low, PET scanning demonstrates hypermetabolism in the cerebellum, lenticular nuclei, and supplementary motor cortex in all carriers of the mutated gene. German Mennonite families with restricted adult-onset dystonia (torticollis and spasmodic dysphonia) have a mutation at 18p, and an X-chromosome mutation has also been described. The unique dopa-responsive dystonia, described below, has been mapped to chromosome 14q ([Nygaard et al](#)).

The relationship of the childhood and adolescent inherited varieties of generalized dystonia to the more common sporadic and restricted dystonias has not been settled, but a few individuals in affected families demonstrate only the most localized forms (e.g., writer's cramp), arising in adulthood. The general rule stated above, however, still holds—namely, that the inherited variety that is tied to chromosome 9q begins early in life in one limb, followed by generalization of the dystonic movements, while in other types, some of which are heritable and some not, the craniocervical or another region is affected early and the condition does not spread.

Clinical Features The first manifestations of the idiopathic generalized disease may be rather subtle. The patient (usually a child between 6 and 14 years of age, less often an adolescent) begins intermittently and usually after activity (late in the day) to invert one foot, to extend one leg and foot in an unnatural way, or to hunch one shoulder, raising the question of a nervous tic. As time passes, however, the motor peculiarity becomes more persistent and interferes increasingly with the patient's activities. Soon the muscles of the spine and shoulder or pelvic girdles become implicated in involuntary spasmodic twisting movements. The spasms are intermittent at first, and in free intervals muscular tone and volitional movements are normal. Indeed, in some instances the muscles are hypotonic. Gradually the spasms become more frequent; finally they are continuous, and the body may become grotesquely contorted. Lateral and rotatory scoliosis are regular secondary deformities. For a time recumbency relieves the spasms, but later position has no influence. The hands are seldom involved, though at times they may be fisted. Cranial muscles do not escape, and in a few instances a slurring, staccato-type speech has even been the initial manifestation. Uncontrollable blepharospasm was the initial disorder in one of our cases; in two others, severe dysarthria and dysphagia were the first signs of the disease, caused by dystonia of the tongue, pharyngeal, and laryngeal muscles. Other manifestations of the movement disorder include torticollis, tortipelvis, dromedary gait, propulsive gait, action tremor, myoclonic jerks during voluntary movement, and mild choreoathetosis of the limbs. Excitement worsens the condition and sleep abolishes it; but as the years pass the postural distortion may become fixed to the point where it does not disappear even in sleep. Tendon reflexes are at all times normal; corticospinal signs are absent; there is no ataxia, sensory abnormality, convulsive disorder, or dementia. Several subgroups have been defined—one type is responsive to L-dopa, another is sex-linked (in the Philippines), and others are associated with parkinsonian symptoms or myoclonus.

Pathology No agreement has been reached concerning the pathologic substrate of the disease. In several reported cases the ferrocacinosis of Hallervorden-Spatz disease, the lesions of Wilson disease or of kernicterus, the état marbré of neonatal hypoxia, or the CT lucencies of familial striatal necrosis were observed in the basal ganglia. Obviously in these cases the dystonia was symptomatic of another disease. However, in the hereditary forms, which are the subject of this section, one cannot be certain of any specific lesions that would account for the clinical manifestations. The brain is grossly normal, and the ventricular size is not increased. According to Zeman, who reviewed all the reported autopsy studies up to 1970, there are no significant changes in the striatum, pallidum, or elsewhere. This does not mean that there are no lesions, only that the techniques being used (qualitative analysis of random sections by light microscopy) are inadequate for their demonstration. Newer methods of identification of striatal cell types have probably not been adequately utilized. Dopamine b-hydroxylase is elevated in the plasma of patients with the autosomal dominant form of the disease and the plasma norepinephrine levels are also raised, but the meaning of these findings is not clear; PET scan changes have already been mentioned.

Treatment Early in the course of the illness, several drugs—including L-dopa, bromocriptine, carbamazepine, diazepam, and tetrabenazine—seem to be helpful, but only in a few patients, and the benefit is not lasting. Intrathecal baclofen has been somewhat more successful in children. The rare hereditary form of dystonia-parkinsonism (described below) responds well to small doses of L-dopa and dopamine agonists and is exceptional in this respect. Burke and coworkers advocate the use of very high doses (30 mg daily or more) of trihexyphenidyl (Artane). Apparently dystonic children can tolerate these high doses if they are raised gradually, by 5-mg increments weekly. In adults, high-dose anticholinergic treatment is less successful but worthy of a trial. Clonazepam is beneficial in some patients with segmental myoclonus. The most impressive results have been obtained by the use of stereotactic techniques to make lesions that are centered in the ventrolateral nuclei of the thalamus or in the pallidum–ansa lenticularis region. Some frightfully deformed children, unable to sit or stand, have been restored to near normalcy for a time. Approximately 70 percent of the patients in Cooper's series were moderately to markedly improved by unilateral or bilateral operations, and, based on a 20-year follow-up study, the improvement was usually sustained. More recent studies have reported a somewhat less favorable but nonetheless clear-cut improvement ([Tasker et al](#); [Andrew et al](#)). The main risk of operation has been a corticospinal tract lesion, produced inadvertently by damaging the internal capsule.

Hereditary Dystonia-Parkinsonism (Segawa Syndrome, Dopa-Responsive Dystonia) Following the description of this disease by Segawa and colleagues in 1976, several other reports have drawn attention to this unique form of hereditary dystonia ([Allen and Knopp](#); [Deonna](#); [Nygaard and Duvoisin](#)). The pattern of inheritance in this disease is probably autosomal dominant, and there is no ethnic predilection. Nygaard and colleagues have found a linkage to chromosome 14q. The dystonic manifestations become evident in childhood, usually between 4 and 8 years of age; females outnumber males in a ratio of 3:2. Often the legs are first affected by intermittent stiffening, with frequent falls and peculiar posturing, sometimes assuming an equinovarus position. The arms become involved as well as the truncal muscles; retrocollis or torticollis may appear. Within 4 to 5 years, all parts of the body including the bulbar muscles are involved. Sometimes parkinsonian features (rigidity, bradykinesia, postural instability) can be detected early in the course of the illness, but characteristically they are added to the clinical picture several years later. Among our own patients and in those of Deonna, there was in some instances a rigidity of the limbs as well as slowness of movement and tremor at rest, all aspects more parkinsonian than dystonic. In still others, the clinical picture has been one of cerebral spastic diplegia. Usually the symptoms disappear after a period of sleep and worsen as the day progresses. This diurnal variation has been a notable feature in some but not all cases. Fluctuations of symptoms with exercise and menses and in the first month of pregnancy are features of some cases.

In one autopsied case, there was a reduction in the amount of tyrosine hydroxylase in the striatum and depigmentation but no cell loss in the substantia nigra ([Rajput et al](#)). The enzyme was also reduced in the striatum, as was the level of dopamine.

The unique feature of this *juvenile dystonia-parkinsonism syndrome*, as it has been called, is the dramatic response of both the dystonic and parkinsonian symptoms to treatment with L-dopa. As little as 10 mg/kg per day may eliminate the movement disorder and permit normal functioning. In this condition, unlike Parkinson disease, the medication can be continued indefinitely without the development of tolerance or wearing-off effects. Segawa disease accounts for some cases that had been reported in the past as juvenile Parkinson disease.

Torticollis and Other Restricted Dyskinesias and Dystonias With advancing age, a large variety of degenerative movement disorders come to light. Supposedly there is loss of neurons in certain parts of the basal ganglia, but this has not been verified by appropriate pathologic studies. Groups of muscles begin to manifest arrhythmic involuntary spasms. The patient's inability to suppress the dystonia and the recognition that it is for the most part beyond voluntary control distinguishes it from the common tics, habit spasms, and mannerisms described in [Chap. 6](#). If the muscle contraction is frequent and prolonged, it is accompanied by an aching pain that may mistakenly be blamed for the spasm and the involved muscle may gradually undergo hypertrophy. Worsening under conditions of excitement and stress and improvement during quiet and relaxation are typical of this group of disorders and contributed in the past to the mistaken notion that the spasms had a psychogenic origin.

The most frequent and familiar type is *torticollis*, wherein an adult, more often a woman, becomes aware of a turning of the head to one side while walking. Usually this condition worsens gradually to a point where it may be more or less continuous, but in some patients it remains mild for years on end. When followed over the years, the condition is observed to remain limited to the same muscles (mainly the scalene, sternocleidomastoid, and upper trapezius). Occasionally torticollis is combined with dystonia of the arm and trunk, tremor, facial spasms, or dystonic writer's cramp.

Other restricted dyskinesias involve the neck in combination with facial muscles, the orbicularis oculi (*blepharospasm* and *blepharoclonus*), the throat and respiratory muscles (“*spastic dysphonia*,” *orofacial dyskinesia*, and *respiratory* and *phonatory spasms*), the hand as in writer's cramp (*graphospasm*) or musician's dystonia, and proximal leg and pelvic girdle muscles, where dyskinesia is elicited by walking. *All these conditions and their treatment are discussed fully in [Chap. 6](#).*

Other Forms of Hereditary Dystonia Several familial movement-induced (kinesogenic) dystonic syndromes and a type that is not kinesogenic and arises suddenly in adolescence, at times with parkinsonian features, have been described (see page 83). There are other degenerative diseases that combine hereditary dystonia with neural deafness and intellectual impairment ([Scribanu and Kennedy](#)) and with amyotrophy in a paraplegic distribution ([Gilman and Romanul](#)).

Two other important diseases that fall into the category of hereditary dystonia have been described in [Chap. 37](#). These are Hallervorden-Spatz disease and calcification of the basal ganglia—and, of course, Wilson disease may have dystonia as a central feature.

SYNDROME OF PROGRESSIVE ATAXIA

This topic was introduced in [Chap. 5](#), and some of the congenital and acute acquired varieties are mentioned on pages 1010, 1021, and 1197. Here we consider only the *chronic progressive forms of cerebellar disease*, many of which are familial and which are more or less confined to this part of the nervous system, although a number of other systems may be involved to a varying degree. Many of these diseases are so chronic that one would expect a close correspondence between their symptomatology and anatomic pathology, yet attempts to determine these relationships have generally been disappointing. Traditionally, the classic examples of chronic progressive cerebellar disease are subsumed under the system atrophies, but no one classification designed to bring precise order to these diseases has proved entirely satisfactory. Wilson wrote that “The group of degenerative conditions strung together by the common feature of ataxia is one for which no very suitable classification has yet been devised”—a statement that is as appropriate today as when it was written almost 60 years ago. Even recent insights provided by the tools of molecular genetics have not fully resolved the problem of classification, mainly because a single gene abnormality may be expressed by a number of different phenotypic syndromes.

Nevertheless, largely through the clinical and pathologic studies of Greenfield and the subsequent studies of Harding, a semblance of order has been brought to the classification of the hereditary ataxias. The classification proposed by Harding represents the most thorough and scholarly effort to meet this goal. Setting aside those of congenital type and those with an underlying metabolic disorder, she has grouped them by age of onset, pattern of heredity, and associated features. A modification of the classifications of Greenfield and of Harding, which is included in the introductory classification of the degenerative diseases (page 1108), is used here. It divides the progressive cerebellar ataxias into three groups—the spinocerebellar ataxias, with unmistakable involvement of the spinal cord (Romberg sign, sensory loss, diminished tendon reflexes, Babinski signs); the pure cerebellar ataxias, with no other associated neurologic disorders; and the complicated cerebellar ataxias, with a variety of retinal, optic nerve, oculo-motor, auditory, pyramidal, extrapyramidal, peripheral nerve, and cerebrocortical accompaniments. Inherited ataxias of early onset (before the age of 20 years) are usually of autosomal recessive type; those of later onset may be autosomal recessive but are usually autosomal dominant.

In the approach to a patient with a heritable ataxia, we find such a classification—based on well-established clinical and pathologic features and patterns of mendelian inheritance—to be the most useful. The molecular genetic revolution of recent years is transforming our understanding of the inherited ataxias and has already disclosed a large number of unexpected relationships between specific genetic defects and other neural and nonneural disorders. These data are incorporated at appropriate points in the following discussion and are summarized at the end of the section.

Early-Onset Spinocerebellar Ataxias (Predominantly Spinal)

Friedreich Ataxia This is the prototype of all forms of progressive spinocerebellar ataxia and accounts for about half of all cases of hereditary ataxia in most large series (86 of 171 cases in Sjögren's series). Friedreich, of Heidelberg, began in 1861 to report on a form of familial progressive ataxia that he had observed among nearby villagers. It was already known through the writings of Duchenne in Paris that locomotor ataxia was the prominent feature of spinal cord syphilis, i.e., tabes dorsalis, and it was Friedreich who demonstrated that a nonsyphilitic hereditary type also existed. This concept was greeted with some skepticism, but soon Duchenne himself affirmed the existence of the new disease and other case reports appeared in England, France, and the United States. In 1882, in a thesis on this

subject by Brousse of Montpellier, Friedreich's name was attached to the new entity.

As new cases appeared, it was noted that in about half of them the disease had its onset before the tenth year and sometimes as early as the second or third; Mollaret could find no examples with onset after the age of 25 years. The disease is invariably and steadily progressive; within 5 years of onset, walking is no longer possible in many cases. Genetic linkage studies of 22 families with three or more affected siblings have led to the assignment of the gene mutation to chromosome 9q13-2 ([Chamberlain et al](#)). A form of Friedreich ataxia of later onset (between 20 and 30 years) and slower progression has been recorded ([DeMichele et al](#)). The gene abnormality, like that of the more classic Friedreich ataxia, is also in the centromeric region of chromosome 9. The gene error related to the chromosome 9 mutation is an expanded repetition of the trinucleotide GAA that codes for a protein called *frataxin*. The current hypothesis is that frataxin is a mitochondrion-associated protein and that the cellular dysfunction is in some way the result of a failure of energy metabolism. Clinical and neuropathologic phenotypes in Friedreich ataxia are associated with diminution or absence of frataxin. Thus despite the variability of the clinical picture, current evidence favors a single gene locus for the disease. The incidence rate among Europeans and North Americans is 1.5 per 100,000 per year.

Clinical Features Ataxia of gait is nearly always the initial symptom. Occasionally the ataxia begins rather abruptly after a febrile illness, and one leg may become clumsy before the other. This “hemiplegic” pattern is exceptional; usually both legs are affected simultaneously. Difficulty in standing steadily and in running are early symptoms, and Wilson has commented on fatigability, leg pains, and postexertional cramps—symptoms that we have seldom elicited. The hands usually become clumsy months or years after the gait disorder, and dysarthric speech appears after the arms are involved (rarely is this an early symptom).

In some patients, pes cavus and kyphoscoliosis precede the neurologic symptoms; in others, they follow by several years. The characteristic foot deformity takes the form of a high plantar arch with retraction of the toes at the metatarsophalangeal joints and flexion at the interphalangeal joints (hammer toes).

A cardiomyopathy is demonstrable in more than half of the patients. The myocardial fibers are hypertrophic and may contain iron-reactive granules (Koeppen). Many of the patients die as a result of cardiac arrhythmia or congestive failure. Kyphoscoliosis and restricted respiratory function are also important contributory causes of death. Harding observed that about 10 percent of these patients have diabetes mellitus and a similar percentage have impaired glucose tolerance.

In the fully developed state, the abnormality of gait is of mixed sensory and cerebellar type, aptly called *tabetocerebellar* by Charcot. According to Mollaret, the author of an authoritative monograph on this disease, the cerebellar component predominates, but in our relatively small series we have been impressed almost as much with the sensory (tabetic) aspect. The patient stands with feet wide apart, constantly shifting position to maintain balance. Friedreich referred to the constant teetering and swaying on standing as static ataxia. In walking, as with all sensory ataxias, the movements of the legs tend to be brusque, the feet resounding unevenly and irregularly as they strike the floor. Closure of the eyes causes the patient to fall (Romberg sign). This reflects the spinal component (posterior columns). Attempts to correct the imbalance may result in abrupt, wild movements. Often there is a rhythmic tremor of the head. The arms are grossly ataxic, and both action and intention tremors are manifest. Speech is slow, slurred, explosive, and finally almost incomprehensible. Breathing, speaking, swallowing, and laughing may be so incoordinate that the patient nearly chokes while speaking. Holmes remarked upon an ataxia of respiration that causes “curious short inspiratory whoops.” Facial, buccal, and arm muscles may display tremulous and sometimes choreiform movements.

Mentation has been preserved in all of our patients. However, emotional lability has been sufficiently prominent to provoke comment by others. Horizontal nystagmus may be present in the primary position and is increased on lateral gaze. Rotatory and vertical nystagmus are rare. Deafness has been recorded, along with vertigo and, more rarely, with inexcitability of the labyrinths and blindness with optic atrophy. Ocular movements usually remain full, and pupillary reflexes are normal. The facial muscles may seem slightly weak, and deglutition may become impaired. Amyotrophy occurs late in the illness and is usually slight, but it may be extreme in patients with an associated neuropathy (see below). The tendon reflexes are abolished in nearly every case; rarely, they may be obtainable when the patient is examined early in the illness. Plantar reflexes are extensor, and flexor spasms may occur even with complete absence of tendon reflexes, indicating that the areflexia is sensory in origin. The abdominal reflexes are usually retained until late in the illness. Loss of vibratory and position sense is invariable from the beginning; later, there may be some diminution of tactile, pain, and temperature sensation as well. Sphincter control is usually preserved.

In one important *variant of Friedreich ataxia* the tendon reflexes are preserved or even hyperactive and the limbs may be spastic. Some of these cases are associated with hypogonadism. The finding of the aberrant gene in these cases on chromosome 9 links them to Friedreich ataxia. Harding found 20 such cases among her 200 familial ataxias at the National Hospital, London. Nevertheless, the distinction between classic Friedreich ataxia and ataxia with retained tendon reflexes is an important one clinically, insofar as kyphoscoliosis and heart disease do not occur in the latter group and the prognosis is better. In other cases, some familial, a spastic paraparesis and optic atrophy are combined with ataxia ([Behr](#)). We would also include here cases of the type described by Hogan and Bauman, in which a progressive cerebellar ataxia was associated with spasticity and other corticospinal tract signs of the legs. Cerebellar atrophy has not been a prominent feature of these cases, and we would adopt the position that they are forms of spinocerebellar degeneration that are transitional between Friedreich ataxia and some of the other heredoataxias with cerebellar atrophy. In the few autopsied cases, the main abnormality has been in the spinal cord and the spinocerebellar (cerebellopetal) tracts, but some in addition show corticospinal tract degeneration.

Other abortive and atypical forms are numerous. Peroneal muscular atrophy is sometimes associated with Friedreich ataxia, as is true of the areflexic dystasia (sensory neuropathy) of Roussy and Levy. These disorders are discussed with the hereditary neuropathies on page 1420. Hereditary forms of optic atrophy, retinitis pigmentosa, deafness, and myoclonus are occasionally combined with Friedreich ataxia as well, but we agree with Skre that they probably represent genetically independent entities. Two of our Friedreich patients had occasional seizures.

Laboratory tests of diagnostic value are sensory nerve conduction velocities and amplitudes, electrocardiography, and chest and spine films (to show heart size and kyphoscoliosis). The CT scans and MRI seldom show a significant degree of cerebellar atrophy; the spinal cord is small, and there is no consistent abnormality of blood or CSF. Visual evoked potentials are abnormal only in patients with associated optic atrophy.

Pathology The spinal cord is thin. The posterior columns and the corticospinal and spinocerebellar tracts are all depleted of medullated fibers, and there is a fibrous gliosis that does not replace the bulk of the lost fibers. The nerve cells in Clarke's column and the large neurons of the dorsal root ganglia, especially lumbosacral ones, are reduced in number—but perhaps not to a degree that would fully explain the posterior column degeneration. The posterior roots are thin. Betz cells are also diminished in some cases, but the corticospinal tracts are relatively intact down to the medullary-cervical junction. Beyond this point, the corticospinal tracts are degenerated, but to a lesser degree than the posterior columns. The nuclei of cranial nerves VIII, X, and XII all exhibit a reduction of cells. Slight to moderate neuronal loss is seen also in the dentate nuclei, and the middle and superior cerebellar peduncles are reduced in size. Some depletion of Purkinje cells in the superior vermis and neurons in corresponding parts of the inferior olivary nuclei can be seen.

Many of the myocardial muscle fibers degenerate and are replaced by fibrous connective tissue. No consistent biochemical abnormalities have been demonstrated.

By way of exploring the anatomic basis of the clinical findings, pes cavus is not different from that seen in other diseases with mild hypertonus of the long extensors and flexors of the feet and in the early-onset hereditary polyneuropathies. These also cause amyotrophy of intrinsic foot muscles when the bones of the feet are still malleable. The kyphoscoliosis is probably due to imbalance of the paravertebral muscles. The tabetic aspects of the disease are explained by the degeneration of large cells in the dorsal root ganglia and the large sensory fibers in nerves, dorsal roots, and the columns of Goll and Burdach. The loss of large neurons in the sensory ganglia also causes abolition of tendon reflexes. The cerebellar ataxia is attributable to a degeneration of the spinocerebellar tracts, the superior vermis, and the dentatorubral pathways in various combinations. Corticospinal lesions account for the weakness and Babinski signs and the pes cavus as well.

Diagnosis Friedreich disease and its variants must be distinguished from the familial cerebellar cortical atrophy, described next, and familial spastic paraparesis with ataxia, as well as from peroneal muscular atrophy and the Levy-Roussy syndrome, which are discussed with the hereditary neuropathies in [Chap. 46](#). Vitamin E deficiency causes a spinocerebellar syndrome with areflexia in children, as detailed in [Chap. 41](#), but it is distinguishable from Friedreich ataxia by the absence of dysarthria and skeletal or cardiac abnormalities. A form of chronic inflammatory demyelinating polyneuropathy has long overtaken tabes dorsalis as the most frequent type of areflexic ataxia; it bears a superficial resemblance to Friedreich ataxia when its onset is in childhood but lacks cerebellar dysarthria and Babinski signs. In late-onset cases, a form of spinocerebellar degeneration related to human T-cell lymphotropic virus type I (HTLV-I), causing so-called tropical spastic paraparesis as well as the vacuolar myelopathy of AIDS, also needs to be included in the differential diagnosis.

Treatment In a double-blind crossover study by Trouillas and associates, the administration of oral 5-hydroxytryptophan was found to significantly modify the cerebellar symptoms. This drug is serotonergic and is known to suppress posthypoxic action myoclonus. Apart from this form of treatment, with which we have had no experience, no therapeutic measures are known to alter the course of the neurologic disease. Heart failure, arrhythmias, and diabetes mellitus are treated by the

usual means. Surgery for scoliosis and foot deformities may be helpful in selected cases.

Predominantly Cerebellar (Cortical) Forms of Hereditary Ataxia

Soon after the publication of Friedreich's descriptions of a spinal type of hereditary ataxia, reports began to appear of somewhat different diseases in which the ataxia was related to degenerative changes in the cerebellum and brainstem rather than the spinal cord. Claims of their independence from the spinal type were based largely on a later age of onset, a more definite hereditary transmission—usually of autosomal dominant type, the persistence or hyperactivity of tendon reflexes, and the more frequent concurrence of ophthalmoplegia, retinal degeneration, and optic atrophy. Several of these clinical features, particularly briskness of tendon reflexes, are alien to the classic form of Friedreich ataxia.

By 1893 Pierre Marie thought it desirable to create a new category of hereditary ataxia that would embrace all of the non-Friedreich cases. He collated the familial cases of progressive ataxia that had been described by Fraser, Nonne, Sanger Brown, and Klippel and Durante (see [Greenfield](#) and [Harding](#) for references) and proposed that all of them were examples of an entity to which he applied the name *heredoataxie cerebelleuse*. Marie's proposition was based almost entirely on clinical observations—not his own but those made by the aforementioned authors. Later, as members of these families died, postmortem examinations disclosed that Marie's hereditary cerebellar ataxia included not one but several disease entities. Indeed, as pointed out by Holmes (1907) and later by Greenfield, in three of the four families the cerebellum showed no significant lesions at all. Yet there was by then no doubt of a separate class of predominantly cerebellar atrophies, some purely cortical and others associated with a variety of noncerebellar lesions.

Pure Cerebellar Cortical Atrophy Holmes in 1907 described a family of 8 siblings, of whom 3 brothers and 1 sister were affected by a progressive ataxia, beginning with a reeling gait and followed by clumsiness of the hands, dysarthria, tremor of the head, and a variable nystagmus. The ataxia began insidiously in the fourth decade and progressed slowly over many years. The late cortical cerebellar atrophy of Marie, Foix, and Alajouanine, reported in 1922, is probably the same disease. In their patients also, the onset was in later life (average age 57 years). The onset was usually insidious, rarely abrupt, and the progress was extremely slow (survival 15 to 20 years). Ataxia of gait, instability of the trunk, tremor of the hands and head, and slightly slowed, hesitant speech conformed to the usual clinical picture of a progressive cerebellar ataxia. Nystagmus was rare. Intelligence was usually preserved. The patellar reflexes were increased in many cases, the ankle jerks were often absent, and the plantar reflexes were said to be of extensor type in some. The last finding, in the absence of hyperreflexia and spasticity, must be accepted with caution, since withdrawal responses are often mistaken for extensor reflexes. In our own practices, sporadic forms of pure cerebellar degeneration have been as common as inherited ones. The differential diagnosis in the nonfamilial cases is quite broad, as discussed at the end of this section.

Postmortem examination of the Holmes-type cases disclosed a symmetrical atrophy of the cerebellum, involving mainly the anterior lobe and vermis, the latter being more affected than the hemispheres. The Purkinje cells were absent in the lingula, centralis, and pyramis of the superior vermis and reduced in number in the quadrangularis, flocculus, biventral, and pyramidal lobes. The other cerebellar cortical neurons and granule cells were diminished in number, but the latter less so. The white matter was slightly pale in myelin stains. The roof nuclei and pontine nuclei were normal. There was cell loss in the dorsal and medial parts of the inferior olivary nuclei. A questionable pallor was noted in the corticospinal and spinocerebellar tracts in myelin stains of the spinal cord. The vermian atrophy and that of adjacent parts of the cerebellum can be visualized with great clarity in MR images ([Fig. 39-3](#)).

Figure 39-3 Familial cortical cerebellar atrophy. T1-weighted MR image in the sagittal plane showing marked atrophy of vermis and enlargement of fourth ventricle. The brainstem is only mildly atrophic. Compare with [Fig. 39-4](#).

Figure 39-4 Olivopontocerebellar atrophy. MRI in the sagittal plane demonstrating both vermian atrophy (short arrow) and smallness of the pons (long arrow). (From Bisese JH: *Cranial MRI*. New York, McGraw-Hill, 1991, by permission.)

The pathologic findings in the cases of Marie, Foix, and Alajouanine were essentially the same. In further reports, both familial and sporadic cases of this type have been collected. The similarity of the pathologic (and clinical) changes to those of *alcoholic cerebellar degeneration* is at once apparent and should always raise the question of an alcoholic-nutritional cause in sporadic cases ([Chap. 41](#)).

Cerebellar Atrophy with Prominent Brainstem Lesions

Sporadic and Familial Olivopontocerebellar Atrophy A sporadically occurring instance of a disorder closely resembling the Holmes type of cortical cerebellar degeneration but with additional features of brainstem atrophy was described in 1900 by Déjerine and André-Thomas, who named it olivopontocerebellar atrophy (OPCA). The onset of symptoms was in the fifth decade of life, and the main manifestations were ataxia—first in the legs, then in the arms and hands and the bulbar musculature—a symptomatology common to all the cerebellar atrophies. As more and more cases of this type were collected (by 1943, Rosenhagen had collected 45 from the literature, to which he added 11 of his own), a *hereditary pattern* (autosomal dominant) was evident in some, and one or more long tracts in the spinal cord were found to have degenerated. About half the cases later developed the symptoms of Parkinson disease with degeneration of nigral cells and, in a few, of striatal cells as well.

Notable findings in both the sporadic (Menzel and Déjerine-Thomas types) and the familial forms of OPCA are the extensive degeneration of the middle cerebellar peduncles, the cerebellar white matter, and the pontine, olivary, and arcuate nuclei; loss of Purkinje cells has been variable ([Fig. 39-4](#)). Most likely this degeneration represents a terminal “dying back” of axons of the pontine and olivary nuclei with secondary myelin degeneration.

The boundaries of the entity of hereditary OPCA have gradually been extended; Konigsmark and Weiner subdivided them into the following types: (1) hereditary (dominant) type of Menzel; (2) hereditary (recessive) type of Fickler-Winkler; (3) hereditary (dominant) type with retinal degeneration; (4) hereditary (dominant) type of Shut-Haymaker, with spastic paraplegia and areflexia; and (5) hereditary (dominant) type with dementia, ophthalmoplegia, and extrapyramidal signs. But even this

classification does not do justice to the variable presentations. To these can be added two additional types: (6) inherited cases of OPCA with neuropathy and slowed eye movements (described by Wadia) and (7) cases with dystonia and a variety of other clinical findings, most of them in single cases (hemiballismus, athetosis, contractures of the legs, fixed pupils, ophthalmoplegia, ptosis, gaze palsy, deafness, retinal degeneration, mental retardation and epilepsy, claw foot and scoliosis, incontinence, parkinsonian symptoms and signs, dementia). Even a neonatal type is known. Some are detailed further on, under “Other Complicated Hereditary Cerebellar Ataxias.”

Cases of *sporadic olivopontocerebellar atrophy* are more common and tend to occur at an older age than the familial ones, and nystagmus, optic atrophy, retinal degeneration, ophthalmoplegia, and urinary incontinence are generally not observed. However, there are numerous variants that include mild extrapyramidal and neuropathic signs, slow eye movements, dystonia, impairment of vertical saccadic eye movements (thus simulating progressive supranuclear palsy), a vocal cord paralysis that is typical of multiple system atrophy, and deafness, of each of which we have seen examples. The relationship of olivopontocerebellar atrophy to *multiple system atrophy* has already been discussed (page 1137), but we would emphasize again that OPCA occurs most often independent of extrapyramidal degeneration. The same uncertainty regarding the significance of cytoplasmic and neuronal inclusions expressed in the discussion of multiple system atrophy pertains to OPCA.

Machado-Joseph-Azorean Disease Aside from the Andrade type of amyloid polyneuropathy, a special form of hereditary ataxia has been described in patients mainly but not exclusively of Portuguese-Azorean origin. One such case was described by Woods and Schaumburg in 1972 under the name *nigrospindental degeneration with nuclear ophthalmoplegia*. The disorder was characterized by an autosomal dominant pattern of inheritance and by a slowly progressive ataxia beginning in adolescence or early adult life, in association with hyperreflexia, extrapyramidal (parkinsonian) rigidity, dystonia, bulbar signs, distal motor weakness, and ophthalmoplegia. There was no impairment of intellect, and in the examples the authors have seen, the extrapyramidal symptoms were mainly rigidity and slowness of movement. There were no signs of corticospinal involvement. The conjunction of a Parkinson syndrome with cerebellar ataxia was reminiscent of certain cases of *multiple system atrophy* except for an earlier age of onset and the prominence of dystonia, amyotrophy, and ophthalmoplegia. Postmortem examination disclosed a degeneration of the dentate nuclei and spinocerebellar tracts and a loss of anterior horn cells and neurons of the pons, substantia nigra, and oculomotor nuclei. The heredoataxia was unaccompanied by signs of polyneuropathy, which was an important feature of the disease in Portuguese emigrants, described earlier by Nakano and colleagues as Machado disease, this being the name of the progenitor of the afflicted family.

A similarly affected Azorean family named Joseph was described by Rosenberg and colleagues (1976) under the name of *autosomal dominant striatonigral degeneration*. The disease had its onset in early adult life and was characterized by progressive ataxia of gait, followed by dysarthria, nystagmus, slowness of eye movements, reduced facial mobility, slow lingual movements, fasciculations of face and tongue, dystonic postures, rigidity of the limbs, cerebellar tremor, hyperreflexia, and Babinski signs. Rosenberg and coworkers considered the disorder to be a striatonigral degeneration on the basis of their findings in one autopsied case. The choice of this designation was unfortunate, insofar as the clinical and pathologic picture was quite unlike that of the striatonigral degeneration reported by Adams and associates. The diagnosis of striatonigral degeneration was also disputed by Nielsen and by Romanul, who were able to study the brain of the patient reported by Rosenberg and colleagues.

Under the name *Azorean disease of the nervous system*, Romanul and colleagues described yet another family of Portuguese-Azorean descent, many members of which were affected by a syndrome comprising a progressive ataxia of gait, parkinsonian features, limitation of conjugate gaze, fasciculations, areflexia, nystagmus, ataxic tremor, and extensor plantar responses; the pathologic changes closely resembled those described by Woods and Schaumburg. Romanul and coworkers compared the genetic, clinical, and pathologic features of their cases with those described in other Portuguese-Azorean families and concluded that all of them represent a single genetic entity with variable expression. This concept of the disease has been corroborated by the further observations of Rosenberg and of Fowler, who studied 20 patients with the Machado-Joseph-Azorean disease over a 10-year period.

This disease is not limited to Azoreans. Cases conforming to the above descriptions have now been observed among black, Indian, and Japanese families ([Sakai et al](#), [Yuasa et al](#), [Bharucha et al](#)). Cancel and colleagues have found an unstable number of CAG repeating sequences on chromosome 14 and named the disorder, which corresponds to Machado-Joseph disease, type 3 spinocerebellar ataxia (SCA 3).

There is no treatment. Early diagnosis of patients at risk is possible by the examination of ocular movements. In asymptomatic patients, Hotson and associates found dysmetric horizontal and vertical saccades similar to those in symptomatic ones. In fully developed cases, the MRI findings are characteristic—reduced width of the superior and middle cerebellar peduncles, atrophy of the frontal and temporal lobes, and smallness of the pons and globus pallidus ([Murata et al](#)).

Dentatorubropallidoluysian Atrophy (DRPLA) This is a rare familial disorder, described mostly in Japan and in small European pockets, in which symptoms of cerebellar ataxia are coupled with those of choreoathetosis and dystonia, but including, in isolated instances, myoclonus, parkinsonism, epilepsy, or dementia. Pathologically there is degeneration of the dentatorubral and pallidoluysian systems ([Smith](#); [Iizuka et al](#)). The main diagnostic consideration when chorea is prominent is the separation of this disorder from Huntington disease ([Warner et al](#)). The gene defect in four European families has been identified as an unstable CAG trinucleotide repeat on chromosome 12 ([Warner et al](#)). As with Huntington chorea, this disease is inherited as an autosomal dominant trait and there is an inverse correlation between the age of onset and the size of the expansion repeat. Diagnosis can be confirmed by means of DNA analysis.

Dentatorubral Degeneration In 1921, Ramsay Hunt published an account of 6 patients (2 of whom were twin brothers) in whom myoclonus was combined with progressive cerebellar ataxia. The age of onset in the 4 nonfamilial cases was between 7 and 17 years, and the cerebellar ataxia followed the myoclonus by an interval of 1 to 20 years. Hunt named this disorder *dyssynergia cerebellaris myoclonica*. In the twin brothers there were signs of Friedreich ataxia; postmortem examination of one of them showed a degeneration of the posterior columns and spinocerebellar tracts but not of the corticospinal tracts. The only lesion in the cerebellum was an atrophy and sclerosis of the dentate nuclei with degeneration of the superior cerebellar peduncles. Louis-Bar and van Bogaert in 1947 reported a similar case, and they noted, in addition to the above findings, degeneration of the corticospinal tracts and loss of fibers in the posterior roots. Thus the pathology was identical to that of Friedreich ataxia except for the more severe atrophy of the dentate nuclei.

Earlier (1914), under the title of *dyssynergia cerebellaris progressiva*, Hunt had drawn attention to a progressive disease in young individuals manifest by what he considered to be a pure cerebellar syndrome. One of the three patients described in this paper died 13 years after the onset of her illness, and necropsy disclosed cavitory lesions in the lenticular nuclei, cerebellum, and pons and a diffuse increase of Alzheimer (type 2) glial cells, associated with nodular cirrhosis of the liver—i.e., findings typical of progressive lenticular degeneration (Wilson disease). Hunt's reports emphasize the hazard of classifying cerebellar ataxias on the basis of clinical findings alone, a point made effectively by Holmes in relation to the hereditary cerebellar ataxia of Marie (see earlier).

Other Complicated Hereditary Cerebellar Ataxias In addition to the ones enumerated earlier, briefly mentioned here are the hereditary ataxias, all rare, with optic atrophy; the autosomal recessive syndrome of cerebellar ataxia with pigmentary retinal degeneration and congenital deafness; an autosomal dominant hereditary ataxia with muscular atrophy, retinal degeneration, and diabetes mellitus; Friedreich ataxia with juvenile parkinsonism; the autosomal recessive ataxia with total albinism; the autosomal recessive ataxia with cataracts, oligophrenia, pyramidal signs, and stunting of growth; and an essential (familial) tremor complicated in later years by cerebellar ataxia. Details regarding these rare ataxias and appropriate references can be found in the monograph on the inherited ataxias edited by Kark et al. Pollock and Kies have described yet another late-life form of hereditary cerebellar ataxia with near global loss of pain and temperature sensation (due to loss of primary sensory afferents).

One adult form of hereditary cerebellar ataxia is paroxysmal in nature; the episodes occur without explanation and last several hours, leaving the patient normal between episodes or with only minimal ataxia of the limbs and nystagmus ([Griggs et al](#)). It is the only cerebellar ataxia that responds to oral acetazolamide (see [Chap. 5](#) and page 1021). Of related interest is spinocerebellar atrophy type 6, in which a mutation occurs on chromosome 19 in the gene that codes for a voltage-gated calcium channel, resulting in progressive ataxia, dysarthria, and loss of proprioception. This gene is also implicated in the acetazolamide-responsive paroxysmal ataxia.

Genetics of the Heredodegenerative Ataxias Probably the many ataxic disorders just described are genetically distinct. As indicated above, *autosomal recessive* Friedreich ataxia is due to an expanded GAA repeat on chromosome 9q ([Campuzano et al](#)). Larger GAA expansions correlate with an earlier age of onset. The direct molecular test for the GAA expansion is useful for diagnosis, particularly for atypical cases with late onset ([Dürr et al](#)). The rarer recessive type that is precipitated by vitamin E deficiency shows GAA repeats on chromosome 8q, which codes for an α -tocopherol transport gene (see page 1224).

Among the *autosomal dominant* cerebellar ataxias of later onset, molecular-gene studies have identified mutant genes at seven chromosomal loci. Five of these eight forms of autosomal dominant ataxia are known to be caused by expanded CAG-trinucleotide repeats (SCA types 1, 3, 6, and 7 and dentatorubropallidoluysian atrophy, or DRPLA). However, the mechanism by which the resultant increase in glutamine components affects cell dysfunction remains speculative. Tabulated below

are the chromosomal loci of the cerebellar atrophies and their genetic terminology and related neural abnormalities:

6p: SCA 1; ophthalmoparesis, pyramidal and extrapyramidal signs; included in this group are most of the olivopontocerebellar atrophies

12q: SCA 2; slowed saccades

12p: Dentatorubropallidoluysian atrophy

14q: SCA 3; the Machado-Joseph phenotype with several allelic variants

16q: SCA 4; sensory neuropathy and pyramidal signs

11centromeric: SCA 5

3p: SCA 7; retinal degeneration

19p: SCA 6; related to the alpha subunit of a voltage-dependent calcium channel; a different mutation at the same locus causes the acetazolamide-responsive episodic ataxia

In addition, several types of autosomal dominant episodic ataxia have been analyzed and found to be linked to chromosomes 12p (a potassium channel gene) and 19p (a calcium channel gene), as mentioned earlier.

Differential Diagnosis Sporadic forms of cerebellar ataxia in adults are in some instances traceable to strokes involving cerebellar pathways ([Safe et al](#)). Some are alcoholic-nutritional in origin, and a few are related to abuse of drugs (especially anticonvulsants, which may in a few cases cause a permanent ataxia). The paraneoplastic variety of cerebellar degeneration enters into the differential diagnosis; as a rule it occurs mostly in women with breast or ovarian cancers and evolves much more rapidly than any of the heredodegenerative forms. The more rapid onset of ataxia and the presence of anti-Purkinje cell antibodies (anti-Yo; page 724) are central to making the distinction. From time to time one observes an idiopathic variety of subacute cerebellar degeneration, particularly in women; clinically this disorder is indistinguishable from the paraneoplastic variety except that no relationship to neoplasm can be discerned ([Ropper](#)). Rare cases of ataxia have been associated with celiac disease and Whipple disease. The ataxias caused by transmissible agents are discussed in [Chap. 33](#), and the metabolic ataxias are discussed further in [Chap. 37](#). Of these, late-onset GM₂ gangliosidosis may simulate a cerebellar degeneration in adults (page 1021).

Treatment has been unsatisfactory and is limited largely to devising strategies to prevent falling. Amantadine 200 mg daily for several months has shown limited benefit in some studies ([Boetz et al](#)).

Hereditary Polymyoclonus

The syndrome of quick, arrhythmic, involuntary single or repetitive twitches of a muscle or group of muscles was described in [Chap. 6](#), where it was pointed out that the condition has many causes. Those due to hereditary metabolic diseases are presented in [Chap. 37](#). Familial forms are known, one of which, associated with cerebellar ataxia, was discussed earlier (dyssynergia cerebellaris myoclonica of Ramsay Hunt). But there is another disease, known as *hereditary essential benign myoclonus*, that occurs in relatively pure form unaccompanied by ataxia (page 108). In the latter condition, it may at times be difficult to evaluate coordination because willed movement is interrupted by the myoclonus and may be mistaken for intention tremor. Only by slowing the voluntary movement can the myoclonus be reduced or eliminated. This myoclonic disease is inherited as an autosomal dominant trait. It becomes manifest early in life; once established, it persists with little or no change in severity throughout life, often with rather little disability. It can, by its natural course, be differentiated from some of the hereditary metabolic diseases such as the Unverricht and Lafora types of myoclonic epilepsy, the lipidoses, tuberous sclerosis, and myoclonic disorders that follow certain viral infections and anoxic encephalopathy. Of interest is the response of this form of movement disorder, just as in the cases of acquired postanoxic myoclonus, to certain pharmacologic agents, notably clonazepam, valproic acid, and 5-hydroxytryptophan, the amino acid precursor of serotonin, particularly when these agents are used in combination.

SYNDROME OF MUSCULAR WEAKNESS AND WASTING WITHOUT SENSORY CHANGES

Motor System Disease

This general term is used to designate a progressive degenerative disorder of motor neurons in the spinal cord, brainstem, and motor cortex, manifest clinically by muscular weakness, atrophy, and corticospinal tract signs in varying combinations. It is a disease of middle life, for the most part, and progresses to death in a matter of 2 to 6 years or longer in exceptional cases.

Customarily, motor system disease is subdivided into several types on the basis of the particular grouping of symptoms and signs. The most frequent form, in which amyotrophy and hyperreflexia are combined, is called *amyotrophic lateral sclerosis*, or *ALS* (*amyotrophy* is the term applied to denervation atrophy and weakness of muscles). Less frequent are cases in which weakness and atrophy occur alone, without evidence of corticospinal tract dysfunction; for these the term *progressive spinal muscular atrophy* is used. When the weakness and wasting predominate in muscles innervated by the motor nuclei of the lower brainstem (i.e., muscles of the jaw, face, tongue, pharynx, and larynx), it is customary to speak of *progressive bulbar palsy* (*bulb* being the old name for the medulla oblongata). In a small proportion of patients the clinical state is dominated for a time by spastic weakness, hyperreflexia, and Babinski signs, lower motor neuron affection becoming apparent at a later stage of the illness. *Primary lateral sclerosis* designates a rare form of motor system disease in which the degenerative process remains confined to the corticospinal pathways ([Pringle et al](#)). The present authors believe that the pure spastic paraplegias without amyotrophy represent a special class of disease, hence they are described separately. There is also a relatively common familial form of spastic paraplegia in which the disease process may be confined to the corticospinal tracts or, in some cases, combined with posterior column or other neurologic signs.

Special types of spinal muscular atrophy are particularly frequent in infancy and childhood. Indeed, they are the leading cause of heritable infant mortality and, after cystic fibrosis, the most frequent form of serious autosomal recessive disease ([Pearn](#)). The best known is the Werdnig-Hoffmann type of *infantile spinal muscular atrophy* (SMA type I); but there are other familial forms beginning in later childhood, adolescence, or adult life (SMA types II and III, or the Wohlfart-Kugelberg-Welander type). Despite the clinical heterogeneity of the heritable childhood spinal muscular atrophies, they all map to a single locus on chromosome 5q—i.e., they are genetically homogeneous ([Gilliam et al](#); [Brzustowicz et al](#)). This group of early-onset spinal muscular atrophies is genetically distinct from familial ALS, in which linkage analysis has identified a gene defect on chromosome 21 ([Siddique et al](#)). In respect to the more common nonfamilial forms, there is no reason to believe that the subgroups are anything other than variants of a single pathologic process—an upper and lower motor neuron degeneration or atrophy of unknown etiology.

History Credit for the original delineation of amyotrophic lateral sclerosis is appropriately given to Charcot. With Joffroy in 1869 and Gombault in 1871, he studied the pathologic aspects of the disease. In a series of lectures given from 1872 to 1874, he gave a lucid account of the clinical and pathologic findings. Although called Charcot disease in France, amyotrophic lateral sclerosis (the term recommended by Charcot) has been preferred in the English-speaking world. Duchenne had earlier (1858) described *labioglossolaryngeal paralysis*, a term that Wachsmuth in 1864 changed to *progressive bulbar palsy*. In 1869 Charcot called attention to the nuclear origin of progressive bulbar palsy, and in 1882 Déjerine established its relationship to amyotrophic lateral sclerosis. Most authors credit Aran and Duchenne with the earliest descriptions of progressive spinal muscular atrophy, which they believed to be of myogenic origin. This interpretation was, of course, incorrect; Cruveilhier, a few years later, noted the slender anterior roots, and soon thereafter the disease was brought into line with ALS as a myelopathic or spinal muscular atrophy.

Amyotrophic Lateral Sclerosis This is a common disease, with an annual incidence rate of 0.4 to 1.76 per 100,000 population. Men are affected somewhat more frequently than women. Most patients are more than 50 years old at the onset of symptoms, and the incidence increases with each decade of life ([Mulder](#)). The disease occurs in a random pattern throughout the world except for a dramatic clustering of patients among inhabitants of the Kii peninsula in Japan and in Guam, where ALS is often combined with dementia and parkinsonism. In about 5 percent of cases the disease is familial, being inherited as an autosomal dominant trait with age-dependent penetrance. The familial cases do not differ in their symptoms and clinical course from nonfamilial ones, although as a group the former have a somewhat earlier age of onset, an equal distribution in men and women, a slightly shorter survival, and a greater tendency for the weakness to begin in the legs.

In the most typical form of ALS, awkwardness in tasks requiring fine finger movements (difficulty with buttons and automobile ignition keys), stiffness of the fingers, and slight weakness or wasting of the hand muscles are the first indications of the disease. Cramping beyond what seems natural and fasciculations of the muscles of the forearm, upper arm, and shoulder girdle also appear. As the weeks and months pass, the other hand and arm may be similarly affected. Before long, the triad of atrophic weakness of the hands and forearms, slight spasticity of the arms and legs, and generalized hyperreflexia—all in the absence of sensory change—leaves little doubt as to the diagnosis. Muscle strength and bulk diminish in parallel; yet despite the amyotrophy, the tendon reflexes are notable for their liveliness. Babinski signs are variably present early in the illness. Abductors, adductors, and extensors of fingers and thumb tend to become weak before the long flexors, on which the handgrip depends, and the dorsal interosseous spaces become hollowed, giving rise to the “cadaveric,” or “skeletal,” hand. The muscles of the upper arm and shoulder girdles are involved later. All this occurs while the thigh and leg muscles seem relatively normal, and there may come a time in some cases when the patient walks about with useless, dangling arms. Later the atrophic weakness spreads to the neck, tongue, pharyngeal, and laryngeal muscles, and eventually those in the trunk and lower extremities yield to the onslaught of the disease.

The affected parts may ache and feel cold, but true paresthesias, except from poor positioning and pressure on nerves, do not occur. Sphincteric control is said to be usually well maintained even after both legs have become weak and spastic, but many of our patients have acquired urinary and sometimes fecal urgency in the advanced stages of the disease. The abdominal reflexes may be elicitable even when the plantar reflexes are extensor. Extreme spasticity is rarely seen. Coarse fasciculations are usually evident in the weakened muscles but may not be noticed by the patient until the physician calls attention to them. Fasciculations are almost never the sole presenting feature of ALS—a clinical truism with which one can reassure physicians and medical students who fear, on the basis of persistent focal muscle twitching, that they are developing the disease.

Other Patterns of Evolution In addition to the special configurations discussed further on, there are many patterns of neuromuscular involvement other than the one just described. A leg may be affected before the hands. A foot drop with weakness and wasting of the pretibial muscles may be incorrectly attributed to peroneal nerve compression until weakness of the gastrocnemius and other muscles betrays a more widespread involvement of lumbosacral neurons. In our experience this crural amyotrophy is nearly as frequent as the brachial-manual type. Another variant is the early involvement of thoracic, abdominal, or posterior neck muscles, the last being one of the main causes of head lolling in older individuals. Yet another pattern is of early diaphragmatic weakness; such cases come to attention because of respiratory failure. The pattern of proximal limb or shoulder girdle amyotrophy with onset at an early age is also well known and simulates muscular dystrophy (Wohlfart-Kugelberg-Welander disease— page 1161). On several occasions we have observed a pattern involving the arm and leg on the same side, first with spasticity and then with some degree of amyotrophy; this is sometimes called the *hemiplegic*, or *Mills, variant*. (More often this condition turns out to be due to multiple sclerosis.) The first manifestations may be a spastic weakness of the legs; a diagnosis of primary lateral sclerosis may be made (discussed further on), and only after a year or two do the hand and arm muscles weaken, waste, and fasciculate. It is cases of this type that led to the inclusion of spastic paraparesis as a variant of ALS. Exceptionally, cramps or fasciculations of the limb muscles may precede recognizable weakness and wasting by a month or two. From time to time, as the disease advances, very mild distal sensory loss is observed in the feet without explanation, but perhaps corresponding to abnormalities of the somatosensory evoked potentials, as noted below; if the sensory loss is definite and an early feature, the diagnosis must remain in doubt. Rarely in North America, ALS has been observed in conjunction with a frontotemporal dementia and with Parkinson disease (page 1126), a complex similar to that observed among the natives of Guam.

The course of this illness, irrespective of its particular mode of onset and pattern of evolution, is inexorably progressive. Half the patients succumb within 3 years of onset and 90 percent within 6 years ([Mulder et al](#)). The variants of motor neuron disease that occur with regularity and have distinguishing clinical features are described below.

Progressive Muscular Atrophy This type of motor system disease is more common in men than in women, in a ratio of 3.6:1 ([Chio et al](#)). In about half the patients, progressive muscular atrophy (PMA) takes the form of a symmetrical (sometimes asymmetrical) wasting of intrinsic hand muscles, slowly advancing to the more proximal parts of the arms; less often, the legs and thighs are the sites of onset of atrophic weakness; less often still, the proximal parts of the limbs are affected before the distal parts. These purely nuclear amyotrophies tend to progress at a slower pace than the usual case of ALS, some patients surviving for 15 years or longer. Chio and colleagues, who analyzed the factors affecting life expectancy in 155 patients with PMA, found that younger patients had a more benign course—the 5-year survival was 72 percent in patients with onset of PMA before age 50 and 40 percent in patients with onset after age 50. Some of the most chronic varieties of PMA are familial. Otherwise they differ from ALS only in that the tendon reflexes are diminished or absent and signs of corticospinal tract disease cannot be detected. Fascicular twitchings and cramping are variably present. The main disease to be distinguished from PMA is the rare immune-mediated motor neuropathy that occurs with or without multifocal block of electrical conduction (page 1411). The presence of a paraproteinemia, specifically IgM with antibodies against the GM₁ ganglioside, or the finding of focal conduction block or sensory nerve abnormalities on the EMG implies the presence of an immune neuropathic disease rather than one of the motor neuron type.

Progressive Bulbar Palsy Here reference is made to a condition in which the first and dominant symptoms relate to weakness of muscles innervated by the motor nuclei of the lower brainstem, i.e., muscles of the jaw, face, tongue, pharynx, and larynx. This weakness gives rise to an early defect in articulation, in which there is difficulty in the pronunciation of lingual (*r, n, l*), labial (*b, m, p, f*), dental (*d, t*), and palatal (*k, g*) consonants. As the condition worsens, syllables lose their clarity and run together until finally speech becomes unintelligible. In other patients, slurring is due to spasticity of the tongue, pharyngeal, and laryngeal muscles or to a combination of atrophic and spastic weakness, as indicated below. Defective modulation of the voice with variable degrees of rasping and nasality is another characteristic. The pharyngeal reflex is lost, and the palate and vocal cords move imperfectly or not at all during attempted phonation. Mastication and deglutition also become impaired; the bolus of food cannot be manipulated and may lodge between the cheek and teeth; and the pharyngeal muscles do not force it properly into the esophagus. Liquids and small particles of food find their way into the trachea or the nose. The facial muscles, particularly of the lower face, weaken and sag. Fasciculations and focal loss of tissue of the tongue are usually early manifestations; eventually the tongue becomes shriveled and lies useless in the floor of the mouth. The chin may also quiver from fascicular twitchings, but diagnosis of the disease should not be made on the basis of fasciculations alone, i.e., in the absence of weakness or atrophy. Fasciculations in themselves may be entirely benign or a part of the syndrome of myokymia or of “continuous muscular activity” (page 1568).

The jaw jerk may be present or exaggerated at a time when the muscles of mastication are markedly weak. In fact, spasticity of the jaw muscles may be so pronounced that the slightest tap on the chin will evoke clonus and blinking; rarely, attempts to open the mouth elicit a “bulldog” reflex (jaws snap shut involuntarily). Spastic weakness of the oropharyngeal muscles may be the initial manifestation of bulbar palsy and may at times surpass signs of atrophic weakness; pseudobulbar signs (pathologic laughter and crying) may reach extreme degrees. This is the only common clinical situation in which spastic and atrophic bulbar palsy coexist. Strangely, the ocular muscles always escape.

As with other forms of motor system disease, the course of bulbar palsy is inexorably progressive. Eventually the weakness spreads to the respiratory muscles and deglutition fails entirely; the patient dies of inanition and aspiration pneumonia, usually within 2 to 3 years of onset. About 25 percent of cases of motor system disease begin with bulbar symptoms, but rarely if ever does the sporadic form of progressive bulbar palsy run its course as an independent syndrome (pure hereditary forms of progressive bulbar palsy in the adult are known but are rare). Practically always, after a few months, the other manifestations of ALS become evident. In general, the earlier the onset of the bulbar involvement in the course of ALS, the shorter the course of the disease.

Primary Lateral Sclerosis This entity, like ALS, is a form of motor neuron disease, although we consider it to be a separate process. Virtually all patients in whom the signs of corticospinal tract degeneration betray the presence of ALS will develop indications of lower motor neuron disease within 1 year, usually earlier. Those who remain with restricted bilateral signs of upper motor neuron disease often turn out to have multiple sclerosis, a slow compression of the spinal cord by spondylosis or meningioma, or the myelopathic form of adrenoleukodystrophy (affected males or female carriers); in a few, tropical spastic paraplegia, HIV myelopathy, or a family history of spastic paraplegia (Strümpell-Lorrain disease, described further on) is uncovered. Approximately 20 percent of these patients, however, have a slowly progressive corticospinal tract disorder that begins with a pure spastic paraparesis; later, and to a lesser degree, the arms and oropharyngeal muscles become involved. These cases have distinctive neuropathologic features and are designated as *primary lateral sclerosis*, a term originally suggested by Erb in 1875. A historical review of the subject appears in the article by Pringle and colleagues.

The typical case begins insidiously in the fifth or sixth decade with a stiffness in one leg, then the other; there is a slowing of gait, with spasticity predominating over weakness as the years go on. Walking is still possible with the help of a cane for many years after the onset, but eventually this condition acquires the characteristic features of a severe spastic paraparesis. Over the years, finger movements become slower, the arms become spastic, and, if the illness persists for decades, speech takes on a pseudobulbar tone. In some patients the illness evolves over a few years. There are no sensory symptoms or signs. Power in the legs is often found to be surprisingly good, the difficulty in locomotion being attributable mainly to rigid spasticity. About half the patients acquire spasticity of the bladder. Pringle and associates suggest that an important diagnostic criterion of the disease is progression for 3 years without evidence of lower motor neuron dysfunction. A rare type of spasticity begins in the oropharyngeal muscles, as mentioned above.

Pathologic studies have disclosed a relatively stereotyped pattern of reduced numbers of Betz cells in the frontal and prefrontal motor cortex, degeneration of the

corticospinal tracts, and preservation of motor neurons in the spinal cord and brainstem ([Beal and Richardson](#), [Pringle et al](#)). The corticospinal tract lesions are identical to those in typical ALS, described further on. Whether some of these cases are examples of late-onset familial spastic paraplegia (see further on) has not been explored with molecular techniques.

As to treatment, an attempt can be made to reduce the spasticity with medications such as baclofen or tizanidine, or subarachnoid infusions of baclofen. Initial intrathecal test doses are given to predict a response to pump infusions of baclofen, but this test may fail; in severe cases, it may be advisable to proceed with a constant infusion for several days. Some degree of improved comfort from a reduction in the extreme rigidity is usually the most that can be expected.

Laboratory Features of Motor Neuron Disease Laboratory investigation of the patient with motor system disease provides useful confirmatory evidence even in the presence of the typical clinical pictures. The EMG, as expected, displays widespread fibrillations and fasciculations (evidence of active denervation and reinnervation), and motor nerve conduction studies reveal only a slight slowing. If the atrophic paresis is restricted to an arm or hand, raising the question of cervical spondylosis, evidence of denervation over many somatic segments favors the diagnosis of ALS. In questionable cases, it is good practice to insist that denervation be demonstrated in at least three limbs before concluding that the process is ALS. Widespread denervation of the paraspinal muscles and genioglossus or facial muscles is also a strong indicator of the disease, but testing of these muscles and interpretation of the tests demands considerable experience. Sensory nerve action potentials should be normal; tests of motor nerve conduction show a normal velocity, but the amplitudes become progressively lower as the disease progresses—in the earliest stages, they too may be normal. The CSF protein is usually normal or marginally elevated. Serum creatine kinase is slightly or moderately elevated in cases with rapidly progressive atrophy and weakness but is just as often normal.

It has become clear that sensory evoked potentials are abnormal in a proportion of patients, but the explanation for this finding is obscure in a disease that clinically and pathologically affects solely the motor system. When the amplitudes of sensory nerve action potentials are reduced, there is usually an underlying entrapment neuropathy or late-life neuropathy. Sensory complaints and minimal sensory loss have been commented on above. Motor evoked potentials that are elicited from the cortex are also prolonged in those with prominent corticospinal signs. In this group, the MRI may show slight atrophy of the motor cortices and wallerian degeneration of the motor tracts ([Fig. 39-5](#)). These changes may be diagnostically useful and appear as subtly increased T2 signal intensity in the posterior limb of the internal capsule, brainstem, and spinal cord, all of which can be missed because of their symmetry.

Figure 39-5 T2-weighted MR image showing signal changes that reflect wallerian change in the corticospinal tracts at the level of the internal capsule (top, arrow) and the pons (bottom) in a case of ALS.

Pathology The principal finding in ALS is a loss of nerve cells in the anterior horns of the spinal cord and motor nuclei of the lower brainstem. Large neurons tend to be affected before small ones. Lost cells are replaced by fibrous astrocytes. Many of the surviving nerve cells are small, shrunken, and filled with lipofuscin. Occasionally, an ill-defined cytoplasmic inclusion body is seen. According to some reports, swelling of the proximal axon is an early finding, presumably antedating visible changes in the cell body itself. The anterior roots are thin, and there is a disproportionate loss of large myelinated fibers in motor nerves ([Bradley et al](#)). The muscles show typical denervation atrophy of different ages. Whitehouse and coworkers found a depletion of muscarinic, cholinergic, glycinergic, and benzodiazepine receptors in regions of the spinal cord where motor neurons had disappeared.

The corticospinal tract degeneration is most evident in the lower parts of the spinal cord, but it can be traced up through the brainstem to the posterior limb of the internal capsule and corona radiata by means of fat stains, which show the macrophages that accumulate in response to the myelin degeneration. There is a loss of Betz cells in the motor cortex; this is evident as frontal lobe atrophy on the MRI in primary lateral sclerosis, but it is not a prominent finding in most cases of ALS ([Kiernan and Hudson](#)). Other fibers in the ventral and lateral funiculi are depleted, imparting a characteristic pallor in myelin stains. Some pathologists have interpreted this as evidence of involvement of nonmotor neurons and hence object to the term *motor system disease*. However, we regard this condition as due to a loss of collaterals of motor neurons that contribute to the lamina propria. One observes the same effect in severe, long-standing poliomyelitis.

Neuropathologic studies of cases of ALS with dementia are few in number. In addition to the usual affection of motor neurons, these cases have shown an extensive neuronal loss, gliosis, and vacuolation involving the premotor area, particularly the superior frontal gyri and the inferolateral cortex of the temporal lobes. The histologic changes of Alzheimer or Pick disease have not been seen in our cases; neurofibrillary degeneration has been observed but is inconsequential in comparison to that seen in the Guamanian Parkinson-dementia-ALS complex ([Finlayson et al](#); [Mitsuyama](#)). Attempts to transmit this ALS-dementia syndrome to subhuman primates have been unsuccessful.

Diagnosis Motor system disease may be simulated by a central spondylotic bar or ruptured cervical disc, but with these latter conditions there is usually pain in the neck and shoulders, limitation of neck movements, and sensory changes; the lower motor neuron affection is restricted to one or two spinal segments. Electromyography is helpful if not decisive in differentiating these disorders, as indicated above. Already mentioned in the diagnosis of ALS is the finding of active denervation in three limbs and in paraspinal, facial, and tongue muscles. A mild hemiparesis or monoparesis due to multiple sclerosis may for a time be difficult to distinguish from early ALS. Progressive spinal muscular atrophy may be differentiated from peroneal muscular atrophy (Charcot-Marie-Tooth neuropathy) by the lack of family history, the complete lack of sensory change, and different EMG patterns. Motor system disease beginning in the proximal limb muscles may be misdiagnosed as a limb-girdle type of muscular dystrophy. The main considerations in relation to progressive bulbar palsy are myasthenia gravis and, less often, polymyositis, muscular dystrophy, and especially the inherited ([Kennedy](#)) type of bulbospinal atrophy, which is discussed further on. The spastic form of bulbar palsy may suggest the pseudobulbar palsy of lacunar disease. A crural form of progressive muscular atrophy may be confused with diabetic polyradiculopathy or polymyositis.

As mentioned earlier, a major consideration is the differentiation of progressive muscular atrophy from chronic motor polyneuropathy with or without multifocal conduction block and related disorders, in which there is an idiopathic motor axonopathy. These distinctions are made by careful, extensive conduction studies and needle EMG examinations ([Chap. 45](#)); they are discussed with the peripheral neuropathies ([Chap. 46](#)). There is also a rare form of subacute poliomyelitis (possibly viral) in patients with lymphoma or carcinoma; it leads to an amyotrophy that progresses to death over a period of several months.

Over the years, the authors have occasionally encountered a patient with a localized amyotrophy of the leg or arm that became arrested and did not advance over a decade or two. Several reports of such a partial spinal amyotrophy have appeared in recent years ([Hirayama et al](#); [Moreno Martinez et al](#)). In a familial variety of pure restricted amyotrophy, only the vocal cords became paralyzed over a period of years in adult life; only later were the hands affected.

Some patients who have recovered from paralytic poliomyelitis may develop progressive muscular weakness 30 or 40 years later; the nature of this relationship is quite obscure. We favor the explanation that atrophy of anterior horn cells with aging brings to light a critically depleted motor neuron population (see further on).

An observation of interest is the finding of a form of progressive spinal muscular atrophy in patients with GM₂ gangliosidosis, the storage disease that presents in infancy as Tay-Sachs disease ([Kolodny and Raghavan](#)). The onset is in late adolescence and early adult life and the atrophic paralysis is progressive, so that this condition is often mistaken for Wohlfart-Kugelberg-Welander disease or ALS. A number of cases of this type have been uncovered in Ashkenazi Jews by the use of lysosomal enzyme analysis.

All these caveats notwithstanding, ALS or the more discrete forms of motor system disease rarely offer any difficulty in diagnosis.

Pathogenesis The pathogenesis of sporadic motor system disease is not known. Of considerable interest has been the discovery of a mutant gene that codes for the enzyme Cu-Zn superoxide dismutase (SOD) in some familial cases of ALS ([Rosen et al](#)), and of an abnormality of the gene for a subunit of the neurofilament protein in others ([Figlewicz et al](#)). Both dominant and rarer recessive forms have been described ([Siddique et al](#), 1996). The former is reflected in a 20 to 50 percent reduction in SOD enzyme activity in affected patients and has led to speculation that an excess of free radicals attributable to the enzyme deficiency allows a slow destruction of neurons. This explanation is probably an oversimplification. An enhancement of excitotoxic glutaminergic activity due to the SOD defect has been proposed as an alternative explanation and is supported by a putative response to treatment with certain glutamate blockers (see further on). Whether these enzymatic and biochemical abnormalities extend to the sporadic type of ALS is unknown, but this approach is providing the most provocative avenues for research.

Trauma, particularly traction injury of an arm, has been reported from time to time as an antecedent event in patients with ALS, but a causative relationship has not been established. Younger and coworkers have reported a higher incidence of paraproteinemia in patients with motor system disease than can be accounted for by chance. Many other examples of disordered immune function have been described in patients with motor system disease, but a coherent explanation of ALS as an autoimmune disease has not emerged. It has never been proved that intoxication with heavy metals (lead, mercury, aluminum) can cause motor system disease. Rare instances of PMA and ALS have been described in patients who had suffered a remote attack of poliomyelitis; these probably represent chance occurrences. There is little evidence that such cases represent a reactivation of the virus or the presence of some other infectious agent. The progressive weakness that occurs some 30 to 40 years after recovery from polio should not be confused with PMA, as indicated above.

Treatment There is no specific treatment for any of the motor neuron diseases; only supportive measures can be utilized. It has been our practice to give the patient some idea of the seriousness of the condition but not to make the devastating statement that it is invariably fatal. Usually it is advisable to give medication of some type “to try to slow the progress of the disease,” even though none is known to be definitely effective. Guanidine hydrochloride and injections of cobra venom, gangliosides, interferons, high-dose intravenous cyclophosphamide, and thyrotropin-releasing hormone are but some of a long list of agents that have been said to arrest the process, but these claims either have been discredited or remain uncorroborated. Bensimon and colleagues have reported that the antiglutamate agent riluzole appears to slow the progression of ALS and improve survival in patients with disease of bulbar onset, but add, at best, only 3 months to life expectancy. This claim requires confirmation but is supported by the slight beneficial effects of riluzole and gabapentin, another glutamate inhibitor, on a model of the familial disease in which a mutant superoxide dismutase has been produced in mice.

In the early stages of ALS, physical therapy is useful in maintaining mobility, but overwork of the muscles generally leads to fatigue and cramps. In the early stages of respiratory failure, nasally applied positive pressure is helpful in assisting sleeping and avoiding daytime somnolence in patients who are able to tolerate the device. Food should be cut into small pieces and dry foods, such as toast, avoided; milk shakes may be tolerated best. A mechanized bed and structural accommodations in the home that facilitate entry of a wheelchair and use of the bath or shower as well as thick-handled utensils make life easier for the patient. The treatment of spasticity, the main concern in primary lateral sclerosis and occasionally a source of difficulty in ALS, is discussed on page 1155.

Complex and sometimes unresolvable decisions must be made by the patient regarding the level of treatment desired as the disease progresses. When the time is appropriate and the patient is receptive or—as often happens with the availability of information on the Internet—the patient raises these issues, we broach the subject of tracheostomy, respiratory support, and feeding tubes and reassure the patient that under no circumstances will he be allowed to suffocate or suffer physically in any other way. In a survey by Albert and colleagues, a surprisingly small number of patients with ALS chose to have a tracheostomy or gastrostomy, and their views early in the illness tended to hold true later. Free access to the neurologist and, if desired by the patient, regular visits for advice can be very reassuring to the patient and family. Hospice-type care is often needed in the last weeks of illness in patients who can otherwise be cared for at home, and morphine or similar drugs as well as antianxiety agents should be used liberally to ease discomfort, respiratory distress, and anxiety in the final days.

Heredofamilial Forms of Progressive Muscular Atrophy and Spastic Paraplegia

Infantile Spinal Muscular Atrophy (Werdnig-Hoffmann Disease) This is the classic form of spinal muscular atrophy of hereditary type. It was first described by Werdnig in 1891 and 1894, by Hoffman in 1893, and, at about the same time, by Thomsen and Bruce. The cases described by these authors all involved infants. Further clinical analyses, however, indicated the inadequacy of this narrow grouping. Brandt, in his study of 112 Danish patients, found that in about one-third the weakness was present at birth, and in 97 the onset was in the first year of life; in 9 patients, the disease was not recognized until after the first year of life. Of the patients with early-onset disease, 53 had died by the end of the first year, but 8 of those with a later onset survived for 4 to 10 years. In 1956 Walton, and later Wohlfart and colleagues and Kugelberg and Welander (see below), identified milder forms of spinal muscular atrophy in which the onset was between 2 and 17 years and walking was still possible in adult life. Byers and Banker, in a study of 52 patients, subdivided them into three groups on the basis of age of onset; in one group the disease was recognized at birth or in the first month or two of life; in a second, between 6 and 12 months; and in a third, after the first year. Again, in their last group, it was not unusual for the patient to survive into adolescence and adult life. In a few of the late-onset types, signs of corticospinal tract involvement are conjoined, and Bonduelle has also included some patients with areflexia, pes cavus, Babinski signs, choreiform movements, and mental retardation in this group. More recently, the designations SMA I, II, and III have been introduced, based largely on the age of onset ([Table 39-1](#)).

Type	Inheritance	Age of onset	Clinical features	Prognosis
SMA I (infantile, Werdnig-Hoffmann)	Autosomal recessive	Prenatal to 6 months	Neonatal hypotonia (flaccid baby); weakness of sucking and swallowing; may have cardiomyopathy; unable to sit	Rarely survives 1 year
SMA II (intermediate type)	Autosomal recessive	6 to 17 months	Proximal weakness; fasciculations; late hand contracture; unable to stand	Variable; death from respiratory complications
SMA III (adult-onset, Kugelberg-Welander)	Autosomal recessive or dominant	1 year to adolescence	Distal motor dysfunction; proximal leg weakness	Slowly progressive; variable outcome
Excessively rapid-onset childhood atrophy?	X-linked (XNL); rapid-onset; late-onset; autosomal dominant	Early childhood	Severe proximal and distal weakness; respiratory involvement; psychomotor retardation	Slowly progressive
Fazio-Londe disease	Autosomal recessive; rarely dominant	Childhood to early adolescence	Progressive bulbar and respiratory failure	Survival 10 years; respiratory failure

Table 39-1 Classification of the spinal muscular atrophies

Familial spinal muscular atrophy that begins in infancy and childhood is inherited mainly as an autosomal recessive trait. Autosomal dominant and X-linked patterns of inheritance have been reported, usually in adults. All of these phenotypes in children have been mapped to the same chromosome: 5q11.2-13.3 ([Brzustowicz et al](#); [Gilliam et al](#); [Munsat et al](#)). Several different mutations have been found in the gene at what has been termed the “survival of motor neuron” (SMN) site. Although the gene product is not known, it has been proposed that the amount of this product may determine the severity of disease. Affected siblings demonstrate very similar clinical patterns of disease, but the same gene error gives rise to very different phenotypes in different families, so that modifying nongenetic attributes must be playing a role.

Finally, it should be reiterated that clinical disorders more or less similar to the spinal muscular atrophies may occur occasionally in certain hereditary metabolic diseases. For example, Johnson and coworkers have described a patient who began experiencing weakness of the legs, cramping, and fasciculations during adolescence in what proved to be a variant of hexosaminidase A (GM₂) deficiency, and biopsy of rectal mucosa showed nerve cells with the typical membranous cytoplasmic bodies of Tay-Sachs disease. Others have reported similar cases. A progressive motor neuron or motor nerve disorder has also been observed in glycogen storage disease affecting anterior horn cells. Motor nerve fibers also suffer damage in metachromatic and globoid body leukoencephalopathies, and, as mentioned, this may occur in adults, in association with paraproteinemia and multiple myeloma and as a paraneoplastic process.

Clinical Manifestations (Early-Onset Classic Type; SMA I) The most frequent form of these spinal muscular atrophies, the severe infantile type, is a common disease, occurring once in every 20,000 live births. After cystic fibrosis, it is the most common cause of death from a recessively inherited disease. Characteristically the infant, usually born normally, is noted from birth to be unnaturally weak and limp (“floppy”). Some mothers report that fetal movement in utero had been less than expected or lacking altogether. In severe cases, arthrogryposis at ankles and wrists or dislocation of the hips is noted at birth (page 1530). The muscle weakness in

these children is generalized from the beginning, and death comes early, usually within the first year. Other infants seem to develop normally for several months before the weakness becomes apparent. In these, the trunk, pelvic, and shoulder-girdle muscles are at first disproportionately affected, while the fingers and hands, toes and feet, and cranial muscles retain their mobility. *Hypotonia* accompanies the weakness, and since passive displacement of articulated parts in testing muscle tone is easier to judge than power of contraction at this early age, it may be singled out as the dominant clinical characteristic. As a rule the tendon reflexes are unobtainable. Volume of muscle is diminished but is difficult to evaluate because of the coverings of adipose tissue. Fasciculations are seldom visible except sometimes in the tongue. Perception of tactile and painful stimuli is undiminished, and emotional and social development measure up to age.

As the months pass, the weakness and hypotonia progress gradually and spread to all of the skeletal muscles except the ocular ones. Intercostal paralysis with a degree of collapse of the chest is the rule. Respiratory movements become paradoxical (abdominal protrusion with chest retraction). The cry becomes feeble, and sucking and swallowing are less efficient. Such infants are unable to sit unless propped, and they cannot hold up their heads without support. They cannot roll over or support their weight when placed on their feet. Their posture is characteristic: arms abducted and flexed at the elbow, legs in the “frog position” with external rotation and abduction at hips and flexion at hips and knees. If the effects of gravity are removed, all muscles continue to contract; i.e., there is paresis, not paralysis. Until late in the illness, these children appear bright-eyed, alert, and responsive.

The disease runs a steadily downhill course. Infants in whom the disease becomes apparent only after several months of life run a less precipitous course than those affected in utero or at birth. Some of the former become able to sit and creep and even to walk with support; those with later onset may survive for several years and even into adolescence or early adult life, as already mentioned.

Laboratory data of confirmatory value are few. Muscle enzymes in the serum are usually normal, rarely elevated. The EMG, if performed at a late enough stage of development, displays fibrillations, proving the denervative basis of the weakness. Motor unit potentials are diminished in number and, in the more slowly evolving cases, some are larger than normal (giant or polyphasic potentials reflecting reinnervation). Motor nerve conduction velocities are normal or fall in the low-normal range (these are normally slower in infants than in adults). Early electrophysiologic studies may also give ambiguous results.

Pathologic Findings Muscle biopsy after 1 month of age reveals a typical picture of group atrophy; shortly after birth this change is difficult to discern. Aside from denervative atrophy, the essential abnormalities are in the anterior horn cells in the spinal cord and the motor nuclei in the lower brainstem. Nerve cells are greatly reduced in number, and many of the remaining ones are in varying stages of degeneration; a few are chromatolytic and contain cytoplasmic inclusions. It is not unusual to see figures of neuronophagia. There is replacement gliosis and secondary degeneration in roots and nerves. Other systems of neurons, including the corticospinal and corticobulbar, remain intact.

Differential Diagnosis *The major problem in diagnosis is to distinguish Werdnig-Hoffmann disease from an array of other diseases that cause hypotonia and delayed motor development in the neonate and infant.* The congenital myopathies (as described in [Chap. 52](#)), the glycogenoses, and disorders of fatty acid metabolism frequently present in this way. The preservation of tendon reflexes and relative lack of progression of muscle weakness distinguish these latter disorders. The muscle biopsy, if studied properly, usually yields the correct diagnosis. Because of the gravity of the diagnosis, muscle biopsy should be performed if there is any suspicion of spinal muscular atrophy. If studied properly, the biopsy usually yields the correct diagnosis.

Certain forms of muscular dystrophy, notably myotonic dystrophy, which is about twice as frequent as Werdnig-Hoffmann disease, may become manifest in the neonatal period and interfere with sucking and motor development ([Chap. 52](#)). As a rule, the weakness is not as severe or diffuse as that in Werdnig-Hoffmann disease. Also, a number of polyneuropathies may cause a serious degree of weakness in early childhood. Unfortunately, in respect to the latter, adequate sensory testing is not possible because of the patients' age, but the CSF protein is often elevated. Again, diagnosis is greatly facilitated by nerve-muscle biopsy and measurement of nerve conduction velocities. The latter are reduced but must be interpreted with caution because of incomplete development of axons and of myelination in the first months of life. The needle EMG examination shows subtle signs of denervation that cannot be easily distinguished from the finding in the spinal muscular atrophies. Examination of parents and siblings may disclose a clinically inapparent neuropathy. Polymyositis of childhood may also simulate both muscular dystrophy and motor neuron disease (page 1482).

Mental retardation with a flaccid rather than spastic weakness of the limbs is another major category of disease that must be distinguished. Also, certain of the polioencephalopathies and leukodystrophies may weaken muscles and abolish tendon reflexes, but usually there is evidence of cerebral involvement. The same may be said of the Down syndrome, cretinism, and achondrodysplasia. Finally, very sick children with celiac disease, cystic fibrosis, and other chronic diseases may be hypotonic to the point of simulating neuromuscular disease. Usually speech is not delayed and tendon reflexes are preserved in these purely medical states, and strength returns as the medical problem is corrected.

There remains, after the assiduous study of the “floppy infant,” a group of cases of hypotonia and motor underdevelopment that cannot be classified. The term *amyotonia congenita* (Oppenheim) was once applied to all of this group but is now obsolete. Walton devised the term *benign congenital hypotonia* to designate patients who manifest limp and flabby limbs in infancy and a delay in sitting up and walking and who improve gradually, some completely and others incompletely. Neither of these terms serves the purpose of precise diagnosis, and so they should be abandoned. It is likely that among this group there are other examples of congenital myopathy that await differentiation by application of modern histochemical, ultrastructural, and genetic techniques.

Chronic Childhood and Juvenile Proximal Spinal Muscular Atrophy (Wohlfart-Kugelberg-Welander Syndrome) This is a somewhat different form of hereditary familial spinal muscular atrophy which, as the name indicates, involves the proximal muscles of the limbs predominantly and is only slowly progressive. It was first clearly separated from other forms of motor system disease and from muscular dystrophy by Wohlfart and by Kugelberg and Welander in the mid-1950s. In about one-third of the cases, the onset is before 2 years of age, and in half, between 3 and 18 years. Males predominate, especially among patients with juvenile and adult onset. The usual form of transmission is by an autosomal recessive gene, but families with dominant and sex-linked inheritance have also been described.

The disease begins insidiously, with weakness and atrophy of the pelvic girdle and proximal leg muscles, followed by involvement of the shoulder girdle and upper arm muscles. Unlike the sporadic form of spinal muscular atrophy, the Wohlfart-Kugelberg-Welander variety is bilaterally symmetrical from the beginning, and fasciculations are observed in only half the cases. Ultimately the distal limb muscles are involved and tendon reflexes are lost. Bulbar musculature and corticospinal tracts are spared, although Babinski signs and an associated ophthalmoplegia (presumably neural) have been reported in rare instances.

The presence of fasciculations and the EMG and muscle biopsy findings—all of which show the characteristic abnormalities of neural atrophy—permit distinction from muscular dystrophy. Cases that have been examined postmortem have shown loss and degeneration of the anterior horn cells.

The disease progresses very slowly, and some patients survive to old age without serious disability. In general, the earlier the onset, the less favorable the prognosis; however, even the most severely affected patients retain the ability to walk for at least 10 years after the onset. Admittedly, it is difficult to make a sharp distinction between these cases of Wohlfart-Kugelberg-Welander disease and certain milder instances of Werdnig-Hoffmann disease with onset in late infancy and early childhood and prolonged survival ([Byers and Banker](#)).

Kennedy Syndrome (Bulbospinal Atrophy) An unusual pattern of *distal atrophy with prominent bulbar signs* and, less often, ocular palsies was first described by Kennedy. The time of onset has varied from childhood to adult age, but most patients have been in their third decade when neurologic symptoms arise. Most cases have shown an X-linked pattern of inheritance and a lesser number an autosomal dominant pattern. The proximal shoulder and hip musculature are involved first by weakness and atrophy, followed by dysarthria and dysphagia in about half of patients. Often muscle cramps or twitching appears before weakness becomes evident. Facial fasciculations are said to be characteristic. The tendon reflexes become depressed and may be absent; a mild sensory neuropathy is almost universal. In the family described by Kaeser, in which 12 members in five generations were affected, the pattern of weakness was shoulder-shank, i.e., scapuloperoneal, for which reason it may be mistaken for muscle dystrophy. The muscular atrophy is associated in two-thirds of patients with gynecomastia (this feature may first identify affected men in a kindred), oligospermia, and sometimes diabetes. The CK level is elevated, sometimes tenfold, and physiologic studies reveal denervation and reinnervation as well as indications of a mild sensory neuropathy.

The fundamental defect is a CAG expansion in the gene that codes for the androgen receptor on the short arm of the X chromosome ([La Spada et al](#)). Lengthened sequences are associated with an earlier age of onset (anticipation, as in Huntington disease) but have no relation to the severity of disease. Androgen receptors have been found on motor neurons of the spinal cord, but the degeneration of motor neurons seems to be independent of this finding. Neuronal inclusions have recently been described, the presumption being that they are aggregations of the abnormally long polyglutamine protein sequences that correspond to the CAG expansion. A family with the bulbospinal phenotype but without the CAG expansion has also been reported ([Paradiso et al](#)). Other features, such as optic atrophy and sensory neuropathy, were present in some members. The diagnosis can be confirmed by genetic testing for the lengthened repeat trinucleotide sequence. Prenatal

diagnosis and identification of female carriers is also possible by genetic testing.

Progressive Bulbar Palsy (Fazio-Londe Syndrome) Fazio in 1892 and Londe in 1893 described the development of a progressive bulbar palsy in children, adolescents, and young adults. There is progressive paralysis of the facial, lingual, pharyngeal, laryngeal, and sometimes ocular muscles. The illness usually presents with stridor and respiratory symptoms, following which facial diplegia, dysarthria, dysphagia, and dysphonia are observed. These become increasingly pronounced until the time of death some years after onset. In a few patients there is a late development of corticospinal signs and sometimes ocular palsies. Also jaw and oculomotor weakness appears occasionally, and in one case there was progressive deafness. The disease is rare, only 24 well-described examples having been recorded in the medical literature by 1992 ([McShane et al](#)). Inheritance may be autosomal dominant, as in Fazio's original case, and rarely X-linked, but it is more likely to be autosomal recessive. Pathologic examination has shown a loss of motor neurons in the hypoglossal, ambiguus, facial, and trigeminal motor nuclei. In a few cases, the nerve cells in the ocular motor nuclei were also diminished. This disease, the few times we have encountered it, had to be differentiated from myasthenia gravis, a pontomedullary glioma, and brainstem multiple sclerosis.

Hereditary Spastic Paraplegia or Diplegia (Strümpell-Lorrain Disease) This disease was described by Seeligmuller in 1874 and later by Strümpell in Germany and Lorrain in France; it has now been identified in nearly every part of the world. The pattern of inheritance is usually autosomal dominant, less often recessive (one family has shown X-linked inheritance), and the onset may be at any age from childhood to the senium. Harding divided the disease into two groups, the more common one beginning before age 35 with a very protracted course and the other with a late onset (40 to 60 years); the latter type often shows sensory loss, urinary symptoms, and kinetic tremor. The clinical picture is that of a gradual development of spastic weakness of the legs with increasing difficulty in walking. The tendon reflexes are hyperactive and the plantar reflexes extensor. In the pure form of the disease, sensory and other nervous functions are entirely intact. If the onset is in childhood, as many cases are, a common orthopedic problem arises of arched and shortened feet and there is a shortening (pseudocontracture) of calf muscles, forcing the child or adolescent to “toe-walk.” In children, the legs appear to be underdeveloped, and they are rather thin in both children and adults. Sometimes the knees are slightly flexed; at other times the legs are fully extended (genu recurvatum) and adducted. Weakness is variable and difficult to estimate. Sphincteric function is usually retained. Subtle sensory loss in the feet has been reported. The arms are variably involved. In some patients, the arms appear to be spared even though the tendon reflexes are lively. In others, the hands are stiff, movements are clumsy, and speech is mildly dysarthric. Conjoined findings such as nystagmus, ocular palsies, optic atrophy, pigmentary macular degeneration, ataxia (both cerebellar and sensory), sensorimotor polyneuropathy, ichthyosis, patchy skin pigmentation, epilepsy, and dementia have all been described in isolated families (see further on).

The few available pathologic studies have shown that, in addition to degeneration of the corticospinal tracts throughout the spinal cord, there is thinning of the columns of Goll, mainly in the lumbosacral regions, and of the spinocerebellar tracts, even when no sensory abnormalities had been detected during life. These were the pathologic findings described by Strümpell in his original (1880) report of two brothers with spastic paraplegia; one of them, in addition, had a cerebellar syndrome, but again there were no sensory abnormalities. A reduction in the number of Betz and anterior horn cells has also been reported.

Inheritance and Pathogenesis Several genetic mutations have given rise to this disease. The uncomplicated autosomal dominant variety has been linked so far to chromosomes 2p, 8q, 14q, and 15q, the 2q variety being most frequent and most often associated with dementia; the recessive variety has been linked to 8p, 15q (the most frequent recessive type), and 16q. The recessive type has the unusual feature of thinning of the corpus callosum. As is true with many similar genetic diseases, the common variety associated with a mutation on 2p shows great variability in clinical presentation within and among families, as has been pointed out by Nielsen and colleagues. Rare X-linked types have been associated with two sites on the long arm of the chromosome, one of which is an allelic variant of the Pelizaeus-Merzbacher gene. In only a few of these kindreds have the genes responsible for disease been identified. A protein called *paraplegin*, a metalloprotease of the mitochondrial inner membrane, has been related to the 16q mutation. A defect in oxidative phosphorylation has been demonstrated in these patients and in theory is related to the abnormal gene product. The genetics of the hereditary spastic paraplegias has recently been reviewed by Figlewicz and Bird.

Differential Diagnosis In the diagnosis of this disorder, one must always consider an indolent spinal cord or foramen magnum tumor, cervical spondylosis, multiple sclerosis (this was the clinical diagnosis in Strümpell's original cases), Chiari malformation, compression of the cord by a variety of congenital bony malformations at the craniocervical junction, and a number of chronic myelitides—Lyme disease, lupus erythematosus, sarcoidosis, acquired immune deficiency syndrome (AIDS), adrenomyeloneuropathy, primary lateral sclerosis (described earlier in this chapter), and tropical spastic paraparesis.

Variants of Familial Spastic Paraplegia The neurologic literature contains a large number of descriptions of familial spastic paraplegia combined with other neurologic abnormalities. Some of the syndromes had developed early in life, in conjunction with moderate degrees of mental retardation. Nevertheless the rest of the neurologic picture appeared many years after birth and was progressive. Some idea of the number of these “hereditary paraplegia-plus” syndromes and the diverse combinations in which they may present is conveyed in the recent review by Gout and colleagues. Again, it is hardly possible to describe each of these symptoms in any degree of detail. The following list includes the best-known entities. But if the term *hereditary spastic paraplegia* is to have any neurologic significance, it should be applied only to the relatively rare, pure form of the progressive syndrome. The more common “atypical” cases—with amyotrophy, cerebellar ataxia, tremors, dystonia, athetosis, optic atrophy, retinal degeneration, amentia, and dementia—should be put in separate categories and their identity retained for nosologic purposes until such time as some biochemical and genetic data related to pathogenesis are forthcoming. Separable also are all the congenital nonprogressive types of spastic diplegia and athetosis. The following list includes the best-known entities:

1. *Hereditary spastic paraplegia with spinocerebellar and ocular symptoms (Ferguson-Critchley syndrome)*. This syndrome is characterized by a disorder of gaze, optic atrophy, cerebellar ataxia, and spastic paraparesis. Most impressive are the manifestations of spinocerebellar ataxia beginning during the fourth and fifth decades of life accompanied by weakness of the legs, alterations of mood, pathologic crying and laughing, dysarthria and diplopia, dysesthesias of limbs, and poor bladder control. The tendon reflexes are lively, with bilateral Babinski signs. Sensation is diminished distally in the limbs. The whole picture resembles multiple sclerosis. In other cases, running through several generations of a family, the extrapyramidal features were more striking; such cases overlap with the following syndromes.
2. *Hereditary spastic paraplegia with extrapyramidal signs*. Action and static tremors, parkinsonian rigidity, dystonic tongue movement, and athetosis of the limbs have all been found in combination with spastic paraplegia. Gilman and Romanul have reviewed the literature on this subject. The picture of parkinsonism with spastic weakness and other corticospinal signs has been the most frequent combination, in the authors' experience.
3. *Hereditary spastic paraplegia with optic atrophy*. This is known as *Behr syndrome* or *optic atrophy- ataxia syndrome*, since cerebellar signs are usually conjoined. Some of the members of the large family reported by Bruyn and Went also had athetosis. The syndrome is transmitted as an autosomal recessive trait, with onset in infancy and slow progression.
4. *Hereditary spastic paraplegia with macular degeneration (Kjellin syndrome)*. Spastic paraplegia with amyotrophy, oligophrenia, and central retinal degeneration constitutes the syndrome described in 1959 by Kjellin. While the mental retardation is stationary, the spastic weakness and retinal changes are of late onset and progressive. When ophthalmoplegia is added, it is called the *Barnard-Scholz syndrome*.
5. *Hereditary spastic paraplegia with mental retardation or dementia*. Many of the children with progressive spastic paraplegia either have been mentally retarded since early life or have appeared to regress mentally as other neurologic symptoms developed. Examples of this syndrome and its variants are too numerous to be considered here but are contained in the review of Gilman and Romanul. The autosomal *recessive syndrome of Sjögren-Larsson*, with the onset in infancy of spastic weakness of the legs in association with mental retardation, stands somewhat apart because of the associated ichthyosis.
6. *Hereditary spastic paraplegia with polyneuropathy*. We have observed several patients in whom a sensorimotor polyneuropathy was combined with unmistakable signs of corticospinal disease. The age of onset was in childhood or adolescence, and the disability progressed to the point where the patient was chair-bound by early adult life. In two of the cases, a sural nerve biopsy revealed a typical hypertrophic polyneuropathy; in a third case there was only a depletion of large myelinated fibers. The syndrome resembles the myeloneuropathy of adrenoleukodystrophy.
7. *Spastic paraparesis with distal muscle wasting (Broyer syndrome)*. This disorder is transmitted as an autosomal recessive trait. Onset is in childhood with amyotrophy of the hands, followed by spasticity and contractures of the lower limbs. Cerebellar signs (mild), athetosis, and deafness may be added.

SYNDROME OF PROGRESSIVE BLINDNESS

There are two main classes of progressive blindness in children, adolescents, and adults: progressive optic neuropathy and retinal (pigmentary or tapetoretinal) degeneration. Of course there are many congenital anomalies and retinal diseases beginning in infancy that result in blindness and microphthalmia. Some of those of neurologic interest were already described briefly in connection with the hereditary spastic paraplegias and in [Chap. 13](#).

Hereditary Optic Atrophy of Leber

Although familial amaurosis was known in the early eighteenth century, it was Leber in 1871 who gave the definitive description of this disease and traced it through many genealogies. The family studies of Nikoskelainen and coworkers indicate that all daughters of carrier mothers become carriers themselves, a type of transmission that is determined by inheritance of defective mitochondrial DNA from the mother ([Wallace et al](#)). In an extensive review of Leber hereditary optic

atrophy by the National Hospital group in London, some of the clinical variations are described. Common to all their cases was the presence of a pathogenic mitochondrial DNA abnormality ([Riordan-Eva et al](#)), but this may occur at one of several sites (page 1140). Thus, Leber optic atrophy has been added to the growing list of mitochondrial diseases, which, as a group, are discussed in detail in [Chap. 37](#).

In most patients, the visual loss begins between 18 and 25 years, but the range of age of onset is much broader. Usually the visual loss has an insidious onset and a subacute evolution, but it may evolve rapidly, so as to suggest a retrobulbar neuritis; moreover, in these latter instances, aching in the eye or brow may accompany the visual loss. Subjective visual phenomena are reported by some. Usually both eyes are affected simultaneously, though in some one eye is affected first, followed by the other after an interval of several weeks or months. In practically all cases, the second eye is affected within a year of the first. In the unimpaired eye, abnormalities of visual evoked potentials may precede impairment of visual acuity ([Carroll and Mastaglia](#)).

Once started, the visual loss progresses over a period of weeks to months. Characteristically, central vision is affected before peripheral, and there is a stage in which bilateral central scotomata are readily demonstrated. Early on, perception of blue-yellow is deficient, while that of red and green is relatively preserved. In the more advanced stages, however, the patients are totally color-blind. Constriction of the fields may be added later. At first there may be swelling and hyperemia of the discs, but soon they become atrophic. Peripapillary vasculopathy, consisting of tortuosity and arteriovenous shunting, is the primary structural change, and this has been present also in asymptomatic offspring of carrier females.

As visual symptoms develop, fluorescein angiography shows shunting in the abnormal vascular bed, with reduced filling of the capillaries of the papillomacular bundle. Although patients are left with dense central scotomata, it is of some importance that the visual impairment is seldom complete; in some patients, relative stabilization of visual function occurs. In a few, there may be a surprising improvement.

Examination of the optic nerve lesion shows the central parts of the nerves to be degenerated from papillae to the lateral geniculate bodies, i.e., the papillomacular bundles are particularly affected. Presumably axis cylinders and myelin degenerate together, as would be expected from the loss of nerve cells in the superficial layer of the retina. Both astrocytic glial and endoneurial fibroblastic connective tissue are increased.

Congenital optic atrophy (of which recessive and dominant forms are known), retrobulbar neuritis, and nutritional optic neuropathy are the main considerations in differential diagnosis.

Retinitis Pigmentosa

This remarkable retinal abiotrophy, known since Helmholtz first invented the ophthalmoscope in 1851, usually begins in childhood and adolescence. Unlike the optic atrophy of Leber, which affects only the third neuron of the visual neuronal chain, retinitis pigmentosa affects all the retinal layers, both the neuroepithelium and pigment epithelium (see [Fig. 13-1](#)). For this combination, Leber proposed the term *tapetoretinal degeneration*, thinking it preferable to *retinitis pigmentosa*, since there is no evidence of inflammation. The incidence of this disorder is two or three times greater in males than in females. Inheritance is more often autosomal recessive than dominant; in the former, consanguinity plays an important part, increasing the likelihood of the disease by approximately 20 times. Sex-linked types are also known. It is estimated that 100,000 Americans are afflicted with this disease.

One form of retinitis pigmentosa is linked to chromosome 3, where the gene for the photosensitive rod-cell protein opsin (which, in combination with vitamin A, forms rhodopsin) is located. When light strikes rhodopsin in the normal eye, the opsin releases vitamin A, and this initiates the sequence of changes that activate the rods. As a consequence of the gene abnormality, the quantity of opsin and rhodopsin in retinitis pigmentosa is reduced; one amino acid building block (proline) in the protein is substituted by histidine ([Dryja et al](#)).

The first symptom is usually an impairment of twilight vision (nyctalopia). Under dim light, the visual fields tend to constrict; but slowly, as the disease progresses, there is permanent visual impairment in all degrees of illumination. The perimacular zones tend to be the first and most severely involved, giving rise to partial or complete ring scotomata. Peripheral loss sets in later. Usually both eyes are affected simultaneously, but cases are on record where one eye was affected first and more severely. Color vision is lost relatively late. The electrical activity of the retina (measured by the electroretinogram) is extinguished, in contrast to the Leber type of optic atrophy, in which it is retained.

Ophthalmoscopic examination shows the characteristic triad of pigmentary deposits that assume the configuration of bone corpuscles, attenuated vessels, and pallor of the optic discs. The pigment is due to clumping of epithelial cells that migrate from the pigment layer to the superficial parts of the retina as the rod cells degenerate. The pigmentary change spares only the fovea, so that eventually the world is perceived by the patient as though he were looking through narrow tubes.

Syndromes to which retinitis pigmentosa may be linked are oligophrenia, obesity, syndactyly, and hypogonadism (Bardet-Biedl syndrome); hypogenitalism, obesity, and mental deficiency (Laurence-Moon syndrome); Friedreich and other types of spinocerebellar and cerebellar ataxia; spastic paraplegia and quadriplegia with Laurence-Moon syndrome; neurogenic amyotrophy, myopia, and color blindness; polyneuropathy and deafness (Refsum disease); deaf mutism; Cockayne syndrome and Bassen-Kornzweig disease; and several mitochondrial diseases—particularly progressive external ophthalmoplegia and Kearns-Sayre syndromes.

Differential diagnosis includes the Batten form of cerebretinal degeneration, Pelizaeus-Merzbacher disease, and Gaucher disease as well as the various forms of ceroid lipofuscinosis and retinal infections such as syphilis, toxoplasmosis, and cytomegalic inclusion disease.

Virtual blindness is the outcome in many cases, but in others the visual failure stops short of that. It is doubtful whether any of the many proposed modes of therapy (sympathectomy, steroids, vitamins A and E) have any effect in halting the progress of the disease.

Stargardt Disease

This is a bilaterally symmetrical, slowly progressive macular degeneration, differentiated from retinitis pigmentosa by Stargardt in 1909. In essence it is a hereditary (usually autosomal recessive) tapetoretinal degeneration or dystrophy (the latter term being preferred by Waardenburg), with onset between 6 and 20 years, rarely later, and leading to a loss of central vision. The macular region becomes gray or yellow-brown with pigmentary spots, and the visual fields show central scotomata. Later the periphery of the retina may become dystrophic. The lesion is well visualized by fluorescein angiography, which discloses a virtually pathognomonic “dark choroid” pattern. Activity in the electroretinogram is diminished or abolished. Both dominantly inherited Stargardt disease and the closely related cone-rod dystrophy have been linked to a defect on chromosome 6p in some families and 13q in others; the less common recessive variety has been mapped to 1p. In the former type, several gene errors code for a transporter protein (termed ABCR) of the photoreceptor.

This disease, with its selective loss of cone function, is in a sense the inverse of retinitis pigmentosa. According to Cohan and associates, it may be associated with epilepsy, Refsum syndrome, Kearns-Sayre syndrome, Bassen-Kornzweig syndrome, or Sjögren-Larsson syndrome, or with spinocerebellar and other forms of cerebellar degeneration and familial paraplegia.

SYNDROME OF PROGRESSIVE DEAFNESS (See pages 296–299)

There is an impressive group of hereditary, progressive cochleovestibular atrophies that are linked to atrophies and degenerations of the nervous system. These are the subject of an informative review by Konigsmark. Such neuro-otologic syndromes must be set alongside a group of five diseases that affect the auditory and vestibular nerves exclusively: dominant progressive nerve deafness; dominant, low-frequency hearing loss; dominant midfrequency hearing loss; sex-linked, early-onset neural deafness; and hereditary episodic vertigo and hearing loss. The last of these is of special interest to neurologists because both balance and hearing are affected.

It should be pointed out that in 70 percent of cases of hereditary deafness, there are no other somatic or neurologic abnormalities. To date, three separate autosomal mutations have been identified that are associated with this pure “nonsyndromic” type of hereditary deafness. In one such family from Costa Rica, the gene codes for protein that regulates the polymerization of actin, the major cytoskeletal component of the hair cells of the inner ear (see review by [Pennisi](#)). More recently, a number of mitochondrial disorders have been associated with deafness alone as well as with a number of the better-characterized mitochondrial syndromes (see [Chap. 37](#)). The age of onset of hearing loss in the pure forms has been variable, extending well into adulthood.

Hereditary Hearing Loss with Retinal Diseases Konigsmark has separated this overall category into three subgroups: patients with typical retinitis pigmentosa, those with Leber optic atrophy, and those with other retinal changes.

With respect to retinitis pigmentosa, four syndromes are recognized. Retinitis pigmentosa in combination with congenital hearing loss is referred to as the Usher syndrome. Retinitis pigmentosa and hereditary hearing loss may also be combined with polyneuropathy (Refsum syndrome); with hypogonadism and obesity (Alstrom syndrome); and with dwarfism, mental retardation, premature senility, and photosensitive dermatitis (Cockayne syndrome).

Hereditary hearing loss with optic atrophy forms the core of four syndromes: dominant optic atrophy, ataxia, muscle wasting, and progressive hearing loss (Sylvester disease); recessive optic atrophy, polyneuropathy, and neural hearing loss (Rosenberg-Chutorian syndrome); optic atrophy, hearing loss, and juvenile diabetes mellitus (Tunbridge-Paley syndrome); and opticocochleodentate degeneration with optic atrophy, hearing loss, quadriplegia, and mental retardation (Nyssen–van Bogaert syndrome).

Hearing loss has also been observed with other retinal changes, two of which might be mentioned: Norrie disease, with retinal malformation, hearing loss, and mental retardation (oculoacousticocerebral degeneration), and Small disease, with recessive hearing loss, mental retardation, narrowing of retinal vessels, and muscle atrophy. In the former, the infant is born blind, with a white vascularized retinal mass behind a clear lens; later the lens and cornea become opaque. The eyes are small and the iris is atrophied. In the latter, the optic fundi show tortuosity of vessels, telangiectases, and retinal detachment. The nature of the progressive generalized muscular weakness has not been ascertained.

Hereditary Hearing Loss with Diseases of the Nervous System There are several conditions in which hereditary deafness accompanies degenerative disease of the peripheral or central nervous system. Those associated with mitochondrial encephalopathies have already been mentioned. The other main ones with autosomal inheritance include the following:

1. *Hereditary hearing loss with epilepsy.* The seizure disorder is mainly one of myoclonus. In one dominantly inherited form, photomyoclonus is associated with mental deterioration, hearing loss, and nephropathy (Hermann disease). In May-White disease, also inherited as an autosomal dominant trait, myoclonus and ataxia accompany hearing loss. Congenital deafness and mild chronic epilepsy of recessive type have also been observed (Latham-Monro disease).
2. *Hereditary hearing loss and ataxia.* Here Konigsmark was able to delineate five syndromes, the first two of which show a dominant pattern of heredity, the last three a recessive pattern: piebaldism, ataxia, and neural hearing loss (Telfer syndrome); hearing loss, hyperuricemia, and ataxia (Rosenberg-Bergstrom syndrome); ataxia and progressive hearing loss (Lichtenstein-Knorr syndrome); ataxia, hypogonadism, mental deficiency, and hearing loss (Richards-Rundles syndrome); ataxia, mental retardation, hearing loss, and pigmentary changes in the skin (Jeune-Tommasi syndrome).
3. *Hereditary hearing loss and other neurologic syndromes.* These include dominantly inherited sensory radicular neuropathy (Denny-Brown); progressive polyneuropathy, kyphoscoliosis, skin atrophy, eye defects (myopia, cataracts, atypical retinitis pigmentosa), bone cysts, and osteoporosis (Flynn-Aird syndrome); chronic polyneuropathy and nephritis (Lemieux-Neemeh syndrome); congenital pain asymbolia and auditory imperception (Osuntokun syndrome); and bulbo pontine paralysis (facial weakness, dysarthria, dysphagia, and atrophy of the tongue with fasciculations) with progressive neural hearing loss. The onset of the last syndrome occurs at 10 to 35 years of age; the pattern of inheritance is autosomal recessive. The disease progresses to death. It resembles the progressive hereditary bulbar paralysis of Fazio-Londe except for the progressive deafness and loss of vestibular responses. Regrettably, in most of these syndromes, there are no data regarding labyrinthine function.

The details of these many syndromes are contained in Konigsmark's review. The syndromes are listed in [Table 15-1](#) and have been summarized here in order to increase awareness of the large number of hereditary neurologic diseases for which the clue is provided by the detection of impaired hearing and labyrinthine functions.

Chapter 40

THE ACQUIRED METABOLIC DISORDERS OF THE NERVOUS SYSTEM

Metabolic Diseases Presenting as a Syndrome of Confusion, Stupor, or Coma

Ischemic-Hypoxic Encephalopathy

Carbon Monoxide Poisoning

High-Altitude (Mountain) Sickness

Hypercapnic Pulmonary Disease

Hypoglycemic Encephalopathy

Hyperglycemia

Hepatic Stupor and Coma (Hepatic or Portal-Systemic Encephalopathy)

Uremic Encephalopathy

Encephalopathy Associated with Sepsis and Burns

Disorders of Sodium, Potassium, and Water Balance

Central Pontine Myelinolysis

Metabolic Diseases Presenting as Progressive Extrapyrarnidal Syndromes

Chronic Acquired (Non-Wilsonian) Hepatocerebral Degeneration

Kernicterus

Hypoparathyroidism

Metabolic Diseases Presenting as Cerebellar Ataxia

Cerebellar Ataxia Associated with Myxedema

Effects of Hyperthermia on the Cerebellum

Cerebellar Syndromes Associated with Celiac-Sprue and Jejunoileal Bypass

Metabolic Disease Presenting as Psychosis and Dementia

Cushing Disease and Corticosteroid Psychoses

Thyroid Encephalopathies

Pancreatic Encephalopathy

Chapter References

An important segment of neurologic medicine, and one that is seen with great frequency in general hospitals, consists of disorders in which a global disturbance of cerebral function (encephalopathy) results from failure of some other organ system—heart and circulation, lungs and respiration, kidneys, liver, pancreas, and the endocrine glands. Unlike the diseases considered in Chap. 37, in which a genetic abnormality affects many organs and tissues, including the brain, the cerebral disorders discussed in this chapter are strictly secondary to derangements of the visceral organs themselves. They stand at the interface of internal medicine and neurology.

Relationships of this type, between an acquired disease of some thoracic or abdominal organ and the brain, have rather interesting implications. In the first place, recognition of the neurologic syndrome may be a guide to the diagnosis of the systemic disease; indeed, the neurologic symptoms may be more informative and significant than the symptoms referable to the organ primarily involved. Moreover, these encephalopathies are often reversible if the systemic dysfunction is brought under control. Neurologists must therefore have an understanding of the underlying medical disorder, for this may provide the means of controlling the neurologic part of the disease. In other words, the therapy for what appears to be a neurologic disease lies squarely in the field of internal medicine—a clear reason why every neurologist should be well trained in internal medicine. Of more theoretical importance, the investigation of the acquired metabolic diseases provides new insights into the chemistry and pathology of the brain. To select a single example, the discovery of an episodic encephalopathy that is associated with advanced liver disease and portocaval shunts opened a vast new area in brain chemistry, pertaining to the effect of ammonia on glutamine metabolism, and has brought to light an intriguing histopathologic change—a relatively pure hyperplasia of protoplasmic astrocytes. Each visceral disease affects the brain in a somewhat different way, and since the pathogenic mechanism is not completely understood in any of them, the study of these metabolic diseases promises rich rewards to the scientist.

In Table 40-1 the acquired metabolic diseases of the nervous system are classified according to their most common modes of clinical expression. Not included are the diseases due to nutritional deficiencies and those due to exogenous drugs and toxins, which can be considered metabolic in the broad sense; these are presented in the following chapters.

I. Metabolic diseases presenting as a syndrome of confusion, stupor, or coma	
A.	Ischemia-hypoxia
B.	Hypoglycemia
C.	Hyperglycemia
D.	Hyperglycemia
E.	Hepatic failure
F.	Renal syndrome
G.	Acidemia
H.	Disorders of sodium, water balance, and osmolality
I.	Hypernatremia
J.	Other metabolic encephalopathies: outbreaks due to dia-
betes mellitus or renal failure; cases after ingestion of toxins of various kinds (e.g., drugs, alcohol, lead, iron, etc.); Addison disease; toxicant-induced encephalopathy	
II. Metabolic diseases presenting as a progressive extrapyramidal syndrome	
A.	Acquired hepatocerebral degeneration
B.	Hypokalemia and kernicterus
C.	Hypernatremia
III. Metabolic diseases presenting as cerebellar ataxia	
A.	Hypokalemia
B.	Hypernatremia
C.	Celiac-sprue disease
IV. Metabolic diseases causing psychosis or dementia	
A.	Cushing disease and steroid encephalopathy
B.	Thyroid psychosis and hypothyroidism
C.	Hyperparathyroidism
D.	Pancreatic encephalopathy (P)

Table 40-1 Classification of the acquired metabolic disorders of the nervous system

METABOLIC DISEASES PRESENTING AS A SYNDROME OF CONFUSION, STUPOR, OR COMA

The *syndrome of impaired consciousness*, its general features, the terms used to describe it, and the mechanisms involved in its genesis are discussed in Chap. 17, which serves as an introduction to this section. There it is pointed out that metabolic disturbances are frequent causes of impaired consciousness and that their presence must always be considered when there are no focal signs of cerebral disease and both the imaging studies and the cerebrospinal fluid (CSF) are normal. Intoxication with alcohol and other drugs figures prominently in the differential diagnosis. *The main features of the reversible metabolic encephalopathies are mental confusion, typified by disorientation and inattentiveness and accompanied in certain instances by asterixis, tremor, and myoclonus, usually without signs of focal cerebral disease such as hemiparesis, hemianopia, hemianesthesia, or a disorder of the cranial nerves.* This state may progress in stages to one of stupor and coma. Slowing of the background rhythms in the electroencephalogram (EEG) reflects the severity of the metabolic disturbance. With few exceptions, usually pertaining to cerebral edema, imaging studies are normal.

Laboratory examinations are highly informative in the investigation of the acquired metabolic diseases. In every patient with symptoms suggestive of a metabolic encephalopathy, the following determinations should be made: serum Na, K, Ca, glucose, BUN, NH₃, and osmolality. If there is evidence of hypoxia or the patient is known to have chronic obstructive airway disease, determination of arterial pH, P_{CO2} and P_{O2} are carried out as well. Serum osmolality can be measured directly or calculated from the values of Na (in meq/L), K (in meq/L), glucose (in mg/dL), and BUN (in mg/dL), using the following formula:

Serum osmolality = 2[(Na) × (K)] + $\frac{\text{glucose}}{18}$ + $\frac{\text{BUN}}{3}$

When there is a discrepancy between the calculated and the directly measured osmolalities, it can be assumed that additional circulating ions are present. Most often they are derived from an exogenous toxin or drug such as mannitol, but renal failure, ketonemia, and an increase of serum lactate may also result in the accumulation

of small molecules that contribute to the serum osmolality.

Where an exogenous toxin is suspected of causing an encephalopathy and in all cases where the cause is unknown, a “toxic screen” of blood and urine, using high-pressure liquid chromatography, should be obtained. A point to be remembered is that the brain may be damaged, even to an irreparable degree, by a disturbance of blood chemistry (e.g., hypoglycemia, hypoxia) that is no longer present when the patient is first seen.

Ischemic-Hypoxic Encephalopathy

Here the basic disorder is a lack of oxygen to the brain, the result of failure of the heart and circulation or of the lungs and respiration. Often both are responsible and one cannot say which predominates; hence the ambiguous allusion in clinical records to “cardiorespiratory failure.”

Ischemic-hypoxic encephalopathy in various forms and degrees of severity is one of the most frequent and disastrous cerebral accidents encountered in the emergency departments and recovery rooms of every general hospital. The medical conditions that most often lead to it are (1) myocardial infarction or ventricular arrhythmia, external or internal hemorrhage, and septic or traumatic shock—in all of which cardiac function fails before that of respiration; (2) suffocation from drowning, strangulation, aspiration of vomitus, food, or blood, compression of the trachea by a mass or hemorrhage, or tracheal obstruction by a foreign body; (3) carbon monoxide (CO) poisoning, in which respiration fails first and then the cardiovascular system; (4) diseases that paralyze the respiratory muscles (Guillain-Barré syndrome, amyotrophic lateral sclerosis, myasthenia, and, in the past, poliomyelitis) or damage the CNS diffusely but the medulla specifically, again with respiratory failure being the initial factor, followed by cardiac failure; and (5) a general anesthesia accident during which the patient is exposed to inspired gas that is oxygen-deficient.

The terms *anoxic*, *anemic*, and *stagnant*, introduced by Barcroft to designate the various forms of anoxia, are now little used in clinical medicine, since the ultimate effect of all three is the same—namely, to deprive the brain and other organs of their critical oxygen supply.

The oxygen content of the blood is the product of hemoglobin concentration and the oxygen saturation of the hemoglobin molecule. At normal temperature and pH, hemoglobin is 90 percent saturated at an oxygen partial pressure of 60 mmHg and still 75 percent saturated at 40 mmHg, i.e., the oxygen saturation curve is not linear.

Reduced to the simplest formulation, a deficient supply of oxygen to the brain is due either to a failure of cerebral perfusion (ischemia) or to a reduced amount of circulating arterial oxygen, the result of diminished oxygen saturation or insufficiency of hemoglobin. The neurologic effects of these two are subtly different.

Physiology of Ischemic and Hypoxic Damage Physiologic mechanisms of a homeostatic nature protect the brain under conditions of both ischemia and hypoxia. When the cerebral perfusion pressure is reduced, there is a compensatory dilatation of resistance vessels, which maintains blood flow at a constant rate (autoregulation). When the cerebral blood pressure falls below 60 to 70 mmHg, increased oxygen extraction still allows normal energy metabolism to continue. In total ischemia, the tissue is depleted of its sources of energy in about 5 min, although longer periods are tolerated under conditions of barbiturate coma and hypothermia. Energy failure due to hypoxia is counteracted by an autoregulatory increase in cerebral blood flow; at a P_{O_2} of 25 mmHg, the increase is approximately 400 percent. A similar increase in flow occurs with a decrease in hemoglobin to 20 percent of normal, but here a decrease in viscosity also facilitates the circulatory response.

Ischemic injury from systemic hypotension differs from that due to pure anoxia. In ischemia, the main damage takes the form of incomplete infarctions in the border zones between major cerebral arteries. With anoxia, neurons in parts of the hippocampus and deep folia of the cerebellum are particularly vulnerable. With more severe degrees of either ischemia or hypoxia, there is first selective damage to certain layers of cortical neurons, and later, generalized damage of all the cerebral cortex, deep nuclei, and cerebellum. Nuclei of the brainstem are relatively resistant to anoxia and hypotension and stop functioning only after the cortex has been badly damaged.

In most of the clinical situations in which the brain is deprived of adequate oxygen, there is a combination of ischemia and hypoxia, but one or the other usually predominates. The cellular pathophysiology of neuronal and tissue damage in cerebral and cerebellar cortices and pallidum under conditions of ischemia is discussed in Chap. 34. Essentially, the mechanism in hypoxic-ischemic injury is an arrest of all aerobic metabolic processes necessary to sustain the Krebs (tricarboxylic acid) cycle and the electron transport system. The neurons, if completely deprived of their source of energy, proceed to catabolize themselves in an attempt to maintain their activity, and in so doing are damaged to a degree that does not permit their survival, i.e., they undergo necrosis. The accumulation of catabolic products (particularly lactic acid) in the interstitial tissue contributes to the parenchymal damage. Also, there is some experimental evidence that excitatory neurotransmitters, particularly glutamate, contribute to the rapid destruction of neurons under conditions of anoxia and ischemia ([Choi and Rothman](#)); how this pertains to clinical situations is uncertain. Ultimately, massive calcium influx through a number of different membrane channels is thought to participate in the process of cellular destruction.

There is also a phenomenon of delayed neurologic deterioration after anoxia that is not understood but may be due to the blockage or exhaustion of some enzymatic process during the period when brain metabolism is restored or even increased (as it is in hyperthermia or possibly with seizures or increased motor activity).

Clinical Features of Anoxic Encephalopathy *Mild degrees of hypoxia without loss of consciousness* induce only inattentiveness, poor judgment, and motor incoordination; in our experience there have been no lasting clinical effects in such cases, though Hornbein and colleagues found, on psychologic testing, a slight decline in visual and verbal long-term memory and mild aphasic errors in Himalayan mountaineers who had ascended to altitudes of 18,000 to 29,000 ft. These observations make the point that profound anoxia may be well tolerated if arrived at gradually. We have seen several patients with advanced pulmonary disease who were fully awake when their arterial oxygen pressure was in the range of 30 mmHg. This level, if it occurs abruptly, causes coma. *An important clinical rule is that degrees of hypoxia that at no time abolish consciousness rarely if ever cause permanent damage to the nervous system* .

In the circumstances of *severe global ischemia with prolonged loss of consciousness*, the clinical effects can be quite variable. With cardiac arrest, for example, consciousness is lost within seconds, but recovery will be complete if breathing, oxygenation of blood, and cardiac action are restored within 3 to 5 min. Beyond 5 min there is usually permanent injury. As shown in experimental models, one of the reasons for the irreversibility of the lesion is swelling of the endothelium and blockage of circulation into the ischemic cerebral tissues (no-reflow phenomenon; [Ames et al](#)). Clinically, however, it is difficult to judge the precise degree of hypoxia, since slight heart action or an imperceptible blood pressure may have served to maintain the circulation to some extent. Hence some individuals have made an excellent recovery after cerebral hypoxia that allegedly lasted 8 to 10 min or longer. Subnormal body temperatures, as might occur when the body is immersed in ice-cold water, greatly prolong the tolerable period of hypoxia. Generally speaking, anoxic patients who demonstrate intact brainstem function (as indicated by normal pupillary light and ciliospinal responses, “doll's-head” eye movements, and oculovestibular reflexes) have a more favorable outlook for recovery of consciousness and perhaps all of their faculties. Conversely, absence of these brainstem reflexes even after circulation and oxygenation have been restored, particularly fixed pupils to light, implies a grave outlook in most circumstances, as elaborated further on.

Most patients who have suffered severe but lesser degrees of hypoxia will have stabilized their breathing and cardiac activity by the time they are first examined; yet they may be profoundly comatose, with the eyes slightly divergent and motionless but with reactive pupils, the limbs inert and flaccid or intensely rigid, and the tendon reflexes diminished. Within a few minutes after cardiac action and breathing have been restored, generalized convulsions and also isolated or grouped myoclonic twitches of muscles may supervene. The seizures, if severe and recurrent, double or treble the oxygen need of cerebral tissues. If the damage is severe, coma persists, decerebrate postures may be present or may occur in response to painful stimuli, and bilateral Babinski signs can be evoked. In the first 24 to 48 h, death may terminate this state in a setting of rising temperature, deepening coma, and circulatory collapse. Tragically, however, the individual may survive for an indefinite period in a state that is variously referred to as cortical death, irreversible coma, or *persistent vegetative state* (see [Chap. 17](#)).

With this severe degree of injury, the cerebral and cerebellar cortices and parts of the thalami are partly or completely destroyed but most often brainstem-spinal structures survive. Some patients remain mute, unresponsive, and unaware of their environment for weeks, months, or years. Long survival is usually attended by some degree of improvement, but the patient appears to know nothing of his present situation and to have lost all past memories, power of reasoning, and capacity for meaningful social interaction and independent existence. One has only to observe such patients and their families to appreciate the gravity of the problem, the heartache, and the tremendous expense of medical care. The only person who does not appear to suffer is the patient.

With lesser degrees of anoxic-ischemic injury, the patient improves after a period of coma. Some of these patients quickly pass through this acute posthypoxic phase and proceed to make a full recovery; others are left with varying degrees of permanent disability.

Brain Death Syndrome (See also [Chap. 17](#)). This represents the most severe degree of oxygen lack, usually caused by circulatory arrest (ischemic anoxia), and is manifest by a state of complete unawareness and unresponsiveness with abolition of all brainstem reflexes. Natural respiration cannot be sustained; only cardiac action and blood pressure are maintained. No electrical activity is seen in the EEG (it is isoelectric). This is the *brain death syndrome* (see page 371). At autopsy one finds that most if not all the gray matter of cerebral, cerebellar, and brainstem structures, and in some instances even of the spinal cord, has been severely damaged.

One must exercise caution in concluding that a patient has irreversible brain damage, because anesthesia, intoxication with certain drugs, and hypothermia may also cause deep coma and an isoelectric EEG but permit recovery. Therefore it is advisable to repeat the clinical and laboratory tests after an interval of a day or two, during which time the results of toxic screening also become available. Such cases have been brought increasingly to public attention because of ethical and moral issues pertaining to discontinuation of medical therapy. The authors' experience corroborates the general notion that the vital functions of patients with the brain death syndrome usually cannot be sustained for more than several days; in other words, the problem settles itself. In exceptional cases, however, the provision of adequate fluid, vasopressor, and respiratory support allows preservation of the somatic organism in a comatose state for longer periods.

Posthypoxic Neurologic Syndromes The permanent neurologic sequelae or *posthypoxic syndromes* observed most frequently are (1) *persistent coma or stupor*, described above, and, with lesser degrees of cerebral injury, (2) *dementia* with or without extrapyramidal signs, (3) *extrapyramidal (parkinsonian) syndrome with cognitive impairment* (discussed in relation to CO poisoning), (4) *choreoathetosis*, (5) *cerebellar ataxia*, (6) *intention or action myoclonus*, and (7) *a Korsakoff amnesic state*. If *ischemic hypoperfusion* dominates, the patient may also display the manifestations of watershed infarctions, situated between the end territories of the major cerebral vessels, the main syndromes being (8) *visual agnosias and "cortical blindness"* and (9) *proximal arm and shoulder weakness*, sometimes accompanied by hip weakness (referred to as a "man in the barrel syndrome"). *Seizures* may or may not continue to be a problem. These sequelae rarely occur in pure form; usually they overlap in various combinations, although any one of them may predominate.

Delayed Postanoxic Encephalopathy This is a relatively uncommon and unexplained phenomenon. Initial improvement, which appears to be complete, is followed after a variable period of time (1 to 4 weeks in most instances) by a relapse, characterized by apathy, confusion, irritability, and occasionally agitation or mania. Most patients survive this second episode, but some of them are left with serious mental and motor disturbances ([Choi](#); [Plum et al](#)). In still other cases there appears to be progression of the initial neurologic syndrome, with additional weakness, shuffling gait, diffuse rigidity and spasticity, sphincteric incontinence, coma, and death after 1 to 2 weeks. Exceptionally, there is yet another chronic syndrome in which an episode of hypoxia is followed by slow deterioration, which progresses for weeks to months until the patient is mute, rigid, and helpless. In such cases the basal ganglia are affected more than the cerebral cortex and white matter ([Dooling and Richardson](#)).

Prognosis of Hypoxic-Ischemic Brain Injury Several logistic models have been developed to predict the outcome of anoxic-ischemic coma. All of them utilize certain simple criteria, involving loss of motor, verbal, and pupillary functions in various combinations. The most often cited and extensive such study, by Levy and colleagues, based on 150 patients who remained in coma for at least 6 h after cardiac arrest, has provided the following guidelines. Mortality from this state is high: 20 percent on the first day and 64 percent at the end of 1 week. Most patients destined to recover awaken within a brief period of time; thus, 17 percent of their patients who recovered were conscious by 3 days, and by 2 weeks the number of conscious patients had risen only by 2 percent. At the other extreme were 31 percent of patients who appeared to be in the vegetative state at 1 day; of this group, 70 percent survived for 1 week, and only 3 patients in all recovered.

Once intoxication is excluded, the presence of fixed dilated pupils and paralysis of eye movement for 24 to 48 h, along with absence of motor responses to painful stimuli, signify irreversible cerebral damage. We have never observed deep coma of this type lasting 5 days or more to be attended by full recovery. The question of what to do with such cases of protracted coma is a societal and not a medical problem. The most that can be expected of the neurologist is to state the level and degree of brain damage, its cause, and the prognosis based on his own and published experience. One prudently avoids heroic, lifesaving therapeutic measures once the nature of this state has been determined with certainty.

Treatment of Hypoxic-Ischemic Encephalopathy Treatment is directed mainly to the prevention of an initial critical degree of hypoxic injury. After a clear airway is secured, the use of cardiopulmonary resuscitation, a cardiac defibrillator, or pacemaker has its place, and every second counts in their prompt utilization. Once cardiac and pulmonary function are restored, there is experimental evidence that reducing cerebral metabolic requirements by hypothermia and by barbiturates or glutamate-blocking medication may prevent the delayed worsening referred to above. However, attempts to demonstrate any of these beneficial effects by controlled trials have failed. Vasodilator drugs and calcium channel blockers are also of no proven benefit. Oxygen may be of value during the first hours but is probably of little use after the blood becomes well oxygenated. Corticosteroids theoretically help to allay brain (possibly cellular) swelling, but again their therapeutic benefit has not been corroborated by clinical trials or practice.

Seizures should be controlled by the methods indicated in [Chap. 16](#). If they are severe, continuous, and unresponsive to the usual anticonvulsant drugs, controlled respiration, continuous infusion of a drug such as midazolam, and eventually neuromuscular blocking agents may have to be used. Often the seizures cease after a few hours and are replaced by polymyoclonus. For the latter; clonazepam, 8 to 12 mg daily in divided doses, may be useful, but the commonly used anticonvulsants have little effect in our experience. This state of spontaneous and stimulus-sensitive myoclonus as well as persistent limb posturing usually presages a poor outcome. The delayed movement-induced myoclonus and ataxic tremor that appear after the patient awakens, described by Lance and Adams, is a special issue that is discussed on page 110. Its treatment requires the use of multiple medications.

Carbon Monoxide Poisoning

Strictly speaking, carbon monoxide (CO) is an exogenous toxin, but it is considered here because it produces a special type of anoxia and one that is frequently associated with delayed neurologic deterioration. The extreme affinity of CO for hemoglobin (over 200 times that of oxygen) drastically reduces the oxygen content of blood and subjects the brain to prolonged hypoxia and acidosis. Cardiac toxicity and hypotension generally follow. Whether CO also has a direct toxic action on neuronal components is not settled. The effects on the brain appear to simulate those caused by cardiac arrest. Neurologists are likely to encounter instances of CO poisoning in burn units and in patients who have attempted suicide or have been exposed accidentally to a faulty furnace or to car exhaust in a closed garage.

Early symptoms include headache, nausea, dyspnea, confusion, dizziness, and clumsiness. These occur when the carboxyhemoglobin level reaches 20 to 30 percent. Exposure to relatively low levels of CO from faulty furnaces and gasoline engines should be suspected as the cause of recurrent headaches and confusion that clear upon hospitalization or other change of venue. A cherry-red color of the skin may appear but is actually an infrequent finding; cyanosis is more common. At slightly higher levels of carboxyhemoglobin, blindness, visual field defects, and papilledema develop, and levels of 50 to 60 percent are associated with coma, decerebrate or decorticate posturing, seizures in a few patients, and generalized slowing of the EEG rhythms. CT scanning is normal or shows mild cerebral edema, or, if hypotension has been profound, the same types of border-zone infarctions that are seen after cardiac arrest.

Delayed neurologic deterioration 1 to 3 weeks (sometimes much longer) after CO exposure occurs more frequently with CO poisoning than with other forms of cerebral hypoxia. In Choi's survey, this feature was observed in 3 percent of 2360 cases of CO poisoning and in 12 percent of those ill enough to be admitted to a hospital. Extrapyramidal features (parkinsonian gait and bradykinesia) predominated. Three-quarters of such patients were said to recover within a year. Discrete lesions centered in the globus pallidus bilaterally and sometimes the inner portion of the putamina are characteristic of CO poisoning that had produced coma ([Fig. 40-1](#)), but similar lesions may be seen after drowning, strangulation, and other forms of anoxia. The common feature among the delayed-relapse patients seems to be a prolonged period of pure anoxia (before the occurrence of ischemia). The basal ganglia lesions may be quite prominent on CT scans even when delayed neurologic sequelae do not occur, but they are almost invariably present between 1 and 4 weeks in patients who develop a delayed extrapyramidal syndrome. In less affected patients, we have seen such lesions resolve.

Figure 40-1 Unenhanced CT scan of brain of a 30-year-old woman who attempted suicide by carbon monoxide inhalation. The only neurologic residua were a mild defect in retentive memory and areas of decreased attenuation in the pallidum bilaterally (arrows).

Because the half-life of CO is greatly reduced by the administration of hyperbaric oxygen at 2 or 3 atmospheres, this treatment is recommended when the carboxyhemoglobin concentration is greater than 40 percent or if the patient is comatose or having seizures ([Myers et al](#)). It is not known whether this treatment reduces the incidence of neurologic sequelae.

High-Altitude (Mountain) Sickness

Acute mountain sickness is another special form of cerebral hypoxia. It occurs when a sea-level inhabitant abruptly ascends to a high altitude. Headache, anorexia, nausea and vomiting, weakness, and insomnia appear at altitudes above 8000 ft; even modest physical exertion at this level causes dyspnea in unconditioned individuals. On reaching higher altitudes, there may be ataxia, tremor, abnormal behavior, drowsiness, and hallucinations. At 16,000 ft, according to Griggs and Sutton, 50 percent of individuals develop asymptomatic retinal hemorrhages, and it is suggested that such hemorrhages may also occur in the cerebral white matter. With more prolonged stays at these altitudes or with further ascent, affected individuals show mental impairment that may progress to coma. Hypoxemia is intensified during sleep, as ventilation diminishes. Reference was made earlier to the observation of Hornbein et al of a mild but possibly lasting memory impairment in even acclimated mountaineers who had been exposed to even higher altitudes for several days.

Chronic mountain sickness, sometimes called Monge disease, is observed in long-term inhabitants of high-altitude mountainous regions. Pulmonary hypertension, cor pulmonale, and secondary polycythemia are the main features. There is usually hypercarbia as well, with the expected mental dullness, slowness, fatigue, nocturnal headache, and sometimes papilledema (see below).

Sedatives, alcohol, and a slightly elevated P_{CO_2} in the blood all reduce one's tolerance to high altitude. Dexamethasone and acetazolamide prevent and counteract mountain sickness to some extent. The most effective preventive measure is acclimatization by a 2- to 4-day stay at intermediate altitudes of 6000 to 8000 ft.

Hypercapnic Pulmonary Disease

Chronic emphysema, chronic fibrosing lung disease, neuromuscular weakness, and in some instances an inadequacy of the respiratory centers lead to chronic respiratory acidosis, with an elevation of P_{CO_2} and a reduction in arterial PO_2 . The clinical syndrome described by [Austen et al](#) comprises *headache, papilledema, mental dullness, drowsiness, confusion, stupor and coma, and asterixis*. Some patients have a degree of superimposed fast-frequency tremor. The headache tends to be generalized, frontal, or occipital in location and intense, persistent, steady, and aching in type; nocturnal occurrence is a feature in some cases. The papilledema is bilateral but may be slightly greater in one eye than in the other, and hemorrhages may encircle the choked disc (a late finding). Visual acuity is undiminished and visual fields are full. Tendon reflexes are lively and plantar reflexes may be extensor. Intermittent drowsiness, indifference to the environment, inattentiveness, reduction of psychomotor activity, inability to perceive all the items in a sequence of events, and forgetfulness constitute the more subtle manifestations of this syndrome and may prompt the family to seek medical help. Such symptoms may last only a few minutes or hours, and one cannot count on their presence at the time of a particular examination. In fully developed cases, the CSF is under increased pressure. P_{CO_2} may exceed 75 mmHg and the O_2 saturation of arterial blood ranges from 85 percent to as low as 40 percent. The EEG shows slow activity in the delta or theta range, which is sometimes bilaterally synchronous.

The mechanism of the cerebral disorder is said to be CO_2 narcosis, but the biochemical details are not all known. Normally the CSF is slightly acidotic in comparison to the blood, and the P_{CO_2} of the CSF is about 10 mmHg higher than that of the blood. With respiratory acidosis, the pH of the CSF falls (in the range of 7.15 to 7.25) and cerebral blood flow increases because of cerebral vasodilatation. However, the brain rapidly adapts to respiratory acidosis through the generation and secretion of bicarbonate by the choroid plexuses. Brain water also increases, mainly in the white matter. In animal models of hypercarbia, NH_3 is elevated, which may explain the similarity of the syndrome to that of hyperammonemia ([Herrera and Kazemi](#)).

The most effective therapeutic measures are ventilation with a positive-pressure device, using oxygen if there is hypoxia; treatment of heart failure; phlebotomy to reduce the viscosity of the blood; and antibiotics to suppress pulmonary infection. Often these measures result in a surprising degree of improvement, which may be maintained for months or years. The danger of administering morphine, which depresses the respiratory center (now insensitive to CO_2), and the danger of oxygen inhalation, which in these circumstances removes the major stimulus to the respiratory center, are now widely recognized; patients treated with oxygen have lapsed into coma.

Unlike pure hypoxic encephalopathy, prolonged coma due to hypercapnia is relatively rare and in our experience has not led to irreversible brain damage. Papilledema and jerky, intermittent lapses of sustained muscular contraction (asterixis) are important diagnostic features. The syndrome is apt to be mistaken for a brain tumor, confusional psychosis of other type, or a disease causing chorea or myoclonus. In the latter case, hypercapnia must be distinguished from other metabolic diseases presenting as chronic extrapyramidal syndromes, as described later in this chapter.

Hypoglycemic Encephalopathy

This condition is relatively infrequent but is an important cause of confusion, convulsions, stupor, and coma; as such, it merits separate consideration as a metabolic disorder of the brain. The essential biochemical abnormality is a critical lowering of the blood glucose. At a level of about 30 mg/dL, the cerebral disorder takes the form of a confusional state, and one or more seizures may occur; at a level of 10 mg/dL, there is profound coma that may result in irreparable injury to the brain if not corrected immediately by the administration of glucose.

The normal brain has a glucose reserve of 1 to 2 g (30 mmol per 100 g of tissue), mostly in the form of glycogen. Since glucose is utilized by the brain at a rate of 60 to 80 mg/min, the glucose reserve will sustain cerebral activity for only about 30 min once blood glucose is no longer available. Glucose is transported from the blood to the brain by a carrier system. When glucose enters the brain, it either undergoes glycolysis or is stored as glycogen. During normal oxygenation (aerobic metabolism), glucose is converted to pyruvate, which enters the Krebs cycle; during anaerobic metabolism, lactate is formed. The oxidation of 1 mol of glucose requires 6 mol of O_2 . Of the glucose taken up by the brain, 85 to 90 percent is oxidized; the remainder enters an amino acid pool and is utilized in the formation of proteins and other substances—notably neurotransmitters, and particularly gamma-aminobutyric acid (GABA).

The brain is the only organ, besides the heart, that suffers severe functional and structural impairment under conditions of hypoglycemia. The pathophysiology of the cerebral disorder has not been fully elucidated. It is known that hypoglycemia reduces O_2 uptake and increases cerebral blood flow. As with anoxia and ischemia, there is experimental evidence that the excitatory amino acid glutamate is ultimately involved in the destruction of neurons. The levels of several brain phospholipid fractions decrease when animals are given large doses of insulin. However, the suggestion that hypoglycemia results in a rapid depletion and inadequate production of high-energy phosphate compounds has not been corroborated; some other glucose-dependent biochemical process must be implicated.

When blood glucose falls, the CNS can utilize nonglucose substrates to a variable extent for its metabolic needs, especially keto acids and intermediates of glucose metabolism such as lactate, pyruvate, fructose, and other hexoses. In the neonatal brain, which has a higher glycogen reserve, keto acids provide a considerable proportion of cerebral energy requirements; this also happens after prolonged starvation. Hypoglycemia also acts on the adrenal glands and the autonomic nervous system to induce a corrective gluconeogenesis. However, in the face of severe and sustained hypoglycemia, these nonglucose substrates are not adequate to preserve the structural integrity of cerebral neurons, and eventually adenosine triphosphate (ATP) is depleted as well. If convulsions occur, they usually do so during a period of mental confusion; the convulsions have been attributed to an altered integrity of neuronal membranes and to elevated NH_3 and depressed GABA and lactate levels ([Wilkinson and Prockop](#)).

Etiology The most common causes of hypoglycemic encephalopathy are (1) accidental or deliberate overdose of insulin or an oral diabetic agent; (2) islet cell, insulin-secreting tumor of the pancreas; (3) depletion of liver glycogen that occasionally follows a prolonged alcoholic binge, starvation, or some form of acute liver disease such as acute nonicteric hepatoencephalopathy of childhood (Reye syndrome); (4) glycogen storage disease of infancy; and (5) an idiopathic hypoglycemia

in the neonatal period and sometimes in infancy. Moderate degrees of hypoglycemia (50 mg/dL) may be observed with chronic renal insufficiency ([Fisher et al](#)). In the past, hypoglycemic encephalopathy was a not infrequent complication of “insulin shock” therapy for schizophrenia. In functional hyperinsulinism, as occurs in anorexia nervosa and in dietary faddism, the hypoglycemia is rarely of sufficient severity or duration to damage the CNS.

Clinical Features When the level of blood glucose has descended to about 30 mg/dL, the initial symptoms appear—nervousness, hunger, flushed facies, sweating, headache, palpitation, trembling, and anxiety; these gradually give way to confusion and drowsiness and occasionally to excitement, overactivity, and bizarre behavior. Many of the early and mild symptoms relate to adrenal and sympathetic overactivity, and therefore some of the manifestations may be muted in diabetic patients with neuropathy. In the next stage, forced sucking, grasping, motor restlessness, muscular spasms, and decerebrate rigidity occur, in that sequence. Myoclonic twitching and convulsions develop in some patients but are by no means the rule. Rarely there are focal cerebral deficits, the pathogenesis of which remains unexplained. Hemiplegia, corrected by intravenous glucose, was observed in 3 of 125 patients who presented with symptomatic hypoglycemia ([Malouf and Brust](#)).

Blood glucose levels of approximately 10 mg/dL are associated with deep coma, dilatation of pupils, pale skin, shallow respiration, slow pulse, and hypotonia of limb musculature—the so-called medullary phase of hypoglycemia. If glucose is administered before this level has been attained, the patient can be restored to normalcy, retracing the aforementioned steps in reverse order. However, once the “medullary phase” is reached, and particularly if it persists for a time before the hypoglycemia is corrected by intravenous glucose or spontaneously as a result of the gluconeogenic activities of the adrenal glands and liver, recovery is delayed for a period of days or weeks and may be incomplete.

The EEG is altered as the blood glucose falls, but the correlations are inexact. There is diffuse slowing in the theta or delta range. During recovery, sharp waves may appear and coincide in some cases with seizures.

A large dose of insulin, which produces intense hypoglycemia, even of relatively brief duration (30 to 60 min), is more dangerous than a series of less severe hypoglycemic episodes from smaller doses of insulin, possibly because the former impairs or exhausts essential enzymes—a condition that cannot then be overcome by large quantities of intravenous glucose.

The major clinical differences between hypoglycemic and hypoxic encephalopathy lie in the setting and the mode of evolution of the neurologic disorder. The effects of hypoglycemia usually unfold more slowly, over a period of 30 to 60 min, rather than in a few seconds or minutes. The recovery phase and sequelae of the two conditions are quite similar. A severe and prolonged episode of hypoglycemia may result in permanent impairment of intellectual function as well as other neurologic residua, like those that follow severe anoxia. We have also observed states of protracted coma as well as relatively pure Korsakoff amnesia. However, one should not be hasty in *prognosis*, for we have observed slow improvement to continue for 1 to 2 years. *Recurrent hypoglycemia*, as with an islet cell tumor, may masquerade for some time as an episodic confusional psychosis or convulsive illness, and diagnosis then awaits the demonstration of low blood glucose or hyperinsulinism in association with the neurologic symptoms.

Lesser degrees and more chronic forms of low blood glucose may produce two other distinct but not mutually exclusive syndromes, according to Marks and Rose, who have written an authoritative monograph on the subject. One of these syndromes, termed *subacute hypoglycemia*, is characterized by drowsiness and lethargy, diminution in psychomotor activity, deterioration of social behavior, and confusion. Oral or intravenous glucose will immediately alleviate the symptoms. In the other syndrome, termed *chronic hypoglycemia*, there is a gradual deterioration of intellectual functions, raising the question of dementia; in some reported instances, tremor, chorea, rigidity, cerebellar ataxia, and rarely signs of lower motor neuron involvement (*hypoglycemic amyotrophy*) are added. The latter feature has not been seen by the authors, who can only refer the reader to the report by Tom and Richardson.

These subacute and chronic forms of hypoglycemia have been observed in conjunction with islet cell hypertrophy and islet cell tumors of the pancreas, carcinoma of the stomach, fibrous mesothelioma, carcinoma of the cecum, and hepatoma. Supposedly an insulin-like substance is elaborated by these nonpancreatic tumors.

Functional or reactive hypoglycemia is the most ambiguous of all syndromes related to low blood glucose. This condition is usually idiopathic but may precede the onset of diabetes mellitus. The rise of insulin in response to a carbohydrate meal is delayed but then causes an excessive fall in blood glucose, to 30 to 40 mg/dL. The symptoms are malaise, fatigue, nervousness, headache, tremor, and so on, which may be difficult to distinguish from anxious depression. Not surprisingly, the term *functional hypoglycemia* has been much abused, being applied indiscriminately to a variety of complaints that would now be called chronic fatigue syndrome. In fact, the syndrome of functional or reactive hypoglycemia is rare and its diagnosis requires the finding of an excessive reaction to insulin, a low blood glucose during the symptomatic period, and a salutary response to oral glucose. Treatment, which consists of a high-protein, low-carbohydrate diet, should be reserved for patients whose symptom complex correlates with pronounced hypoglycemia as documented by a 5-h glucose tolerance test.

Pathologically, in all forms of hypoglycemic encephalopathy, the major damage is to the cerebral cortex. Cortical nerve cells degenerate and are replaced by microgliaocytes and astrocytes. The distribution of lesions is similar, though probably not identical to that in hypoxic encephalopathy. (It appears that the cerebellar cortex is less vulnerable to hypoglycemia than to hypoxia.) Auer has described the ultrastructural changes in neurons resulting from experimental hypoglycemia; with increasing duration of hypoglycemia and EEG silence, there are mitochondrial changes, first in dendrites and then in nerve cell soma, followed by nuclear membrane disruption leading to cell death.

Treatment of all forms of hypoglycemia obviously consists of correction of the hypoglycemia at the earliest possible moment. It is not known whether hypothermia or other measures will increase the safety period in hypoglycemia or alter the outcome.

Hyperglycemia

Two syndromes have been defined, mainly in diabetics: (1) hyperglycemia with ketoacidosis and (2) hyperosmolar nonketotic hyperglycemia.

In *diabetic acidosis* the familiar picture is one of dehydration, fatigue, weakness, headache, abdominal pain, dryness of the mouth, stupor or coma, and Kussmaul type of breathing. Usually the condition has developed over a period of days in a patient known or proven to be diabetic. Insulin has often been omitted. The blood glucose level is found to be more than 400 mg/dL, the pH of the blood less than 7.20, and the bicarbonate less than 10 meq/L. Ketone bodies and b-hydroxybutyric acid are elevated in the blood and urine, and there is a marked glycosuria. The prompt administration of insulin and repletion of intravascular volume correct the clinical and chemical abnormalities over a period of hours.

Of considerable interest is a small group of patients with diabetic ketoacidosis, such as those reported by Young and Bradley, in whom deepening coma and cerebral edema develop as the elevated blood level of glucose is corrected. This condition, which is indicated by rising CSF pressure, has been attributed by Prockop to an accumulation of fructose and sorbitol in the brain. The latter substance, a polyol that is formed during hyperglycemia, crosses membranes slowly, but once it does so is said to cause a shift of water into the brain and an intracellular edema. However, according to Fishman, the increased polyols in the brain in hyperglycemia are not present in sufficient concentration to be important osmotically; they may induce other metabolic effects related to the encephalopathy. These are matters of conjecture, since the increase of polyols has never been found. The edema in this condition is probably due to reversal of the osmolality gradient from blood to brain, which occurs with rapid correction of hyperglycemia. The pathophysiology of the cerebral disorder in diabetic ketoacidosis is not fully understood. No consistent cellular pathology of the brain has been identified in the cases we have examined. Factors such as ketosis, tissue acidosis, hypotension, hyperosmolality, and hypoxia have not proved to be causative. Attempts at therapy by the administration of urea, mannitol, salt-poor albumin, and dexamethasone are usually unsuccessful, though recoveries are reported.

In *hyperosmolar nonketotic hyperglycemia*, the blood glucose is extremely high, over 600 mg/dL, but ketoacidosis does not develop or is mild. Osmolality is usually around 350 mosmol. There is also hemoconcentration and prerenal azotemia. Appreciation of the neurologic syndrome is generally credited to Wegierko, who published descriptions of it in 1956 and 1957. Most of the patients are elderly diabetics, but some were not previously known to have been diabetic. An infection, enteritis, pancreatitis, or a drug known to upset diabetic control (thiazides, prednisone, phenytoin) leads to polyuria, fatigue, confusion, stupor, and coma. Often the syndrome arises in conjunction with the combined use of corticosteroids and phenytoin (which inhibits insulin release), for example, in elderly patients with brain tumors. The use of osmotic diuretics enhances the risk. If the patient is seen before coma supervenes, seizures and focal signs such as a hemiparesis, a hemisensory defect, or a homonymous visual field defect erroneously suggest the possibility of a stroke. The mortality rate has been as high as 40 percent. Fluids should be replaced cautiously, using isotonic saline and potassium. Correction of the markedly elevated blood glucose requires relatively small amounts of insulin, since these patients often do not have a high degree of insulin resistance.

Hepatic Stupor and Coma (Hepatic or Portal-Systemic Encephalopathy)

Chronic hepatic insufficiency with portocaval shunting of blood is often punctuated by episodes of stupor, coma, and other neurologic symptoms—a state that is referred to as *hepatic stupor, coma, or acute hepatic encephalopathy*. This state complicates all varieties of liver disease. Less widely known is the fact that a surgical portal-systemic shunt (Eck fistula) is attended by the same clinical picture, in which case the liver itself may be little affected. Also, there are a number of hereditary hyperammonemic syndromes, usually presenting in infancy or childhood (see [Chap. 37](#)), that lead to episodic coma with or without seizures. In all these states, it is common for an excess of protein, derived from the diet or gastrointestinal hemorrhage, to induce or worsen the encephalopathy. Additional predisposing factors are hypoxia, hypokalemia, metabolic alkalosis, excessive diuresis, use of sedative hypnotic drugs, and constipation. Reye syndrome, a special type of acute nonicteric hepatic encephalopathy of children, is also associated with very high levels of ammonia in the blood (see further on in this chapter).

Clinical Features The clinical picture of subacute or chronic hepatic encephalopathy consists essentially of a derangement of consciousness, presenting first as mental confusion with decreased psychomotor activity, occasionally with hyperactivity, followed by progressive drowsiness, stupor, and coma. The confusional state, before coma supervenes, is frequently combined with a characteristic intermittency of sustained muscle contraction; this phenomenon, which was originally described in patients with hepatic stupor by Adams and Foley and called *asterixis* (from the Greek *sterixis*, a “fixed position”), is now recognized as a sign of various metabolic encephalopathies (page 107). It is conventionally demonstrated by having the patient hold his arms outstretched with the wrists extended, but the same tremor can be elicited by any sustained posture, including that of the protruded tongue. A variable, fluctuating rigidity of the trunk and limbs, grimacing, suck and grasp reflexes, exaggeration or asymmetry of tendon reflexes, Babinski signs, and focal or generalized seizures round out the clinical picture.

The EEG is a sensitive and reliable indicator of impending coma, becoming abnormal during the earliest phases of the disordered mental state. The usual EEG abnormality consists of paroxysms of bilaterally synchronous slow or triphasic waves, in the delta range, which at first predominate frontally and are interspersed with alpha activity and later, as the coma deepens, displace all normal activity ([Fig. 2-3H](#), page 30). A small number of patients show only random high-voltage asynchronous slow waves.

This syndrome of hepatic encephalopathy is remarkably diverse in its clinical presentation. It usually evolves over a period of days to weeks and often terminates fatally; or, with appropriate treatment, the symptoms may regress completely or only partially and then fluctuate in severity for several weeks or months. Persistent hepatic coma of the latter type proves fatal in about half of the patients ([Levy et al](#)). In many patients, the syndrome is relatively mild and does not evolve beyond the stage of mental dullness and confusion, with asterixis and EEG changes. In yet others, a subtle disorder of mood, personality, and intellect may be protracted over a period of many months or even years; this chronic but nevertheless reversible mental disturbance need not be associated with overt clinical signs of liver failure (mainly jaundice and ascites) or other neurologic signs. Characteristically in these patients an extensive portal-systemic collateral circulation can be demonstrated (hence the term *portal-systemic encephalopathy*) and an association established between the mental disturbance and an intolerance to dietary protein and raised blood ammonia levels ([Summerskill et al](#)).

Finally, there is a group of patients (most of whom have experienced repeated attacks of hepatic coma) in whom an *irreversible* mild dementia and a disorder of posture and movement (grimacing, tremor, dysarthria, ataxia of gait, choreoathetosis) gradually appear. This condition of *chronic acquired hepatocerebral degeneration* must be distinguished from other dementing and extrapyramidal syndromes (see further on). A few cases of isolated spastic-ataxic paraplegia (so-called *hepatic myelopathy*) have also been described (page 1329).

The concentrations of blood NH_3 , particularly if measured repeatedly in arterial blood samples, usually are well in excess of 200 mg/dL, and the severity of the neurologic and EEG disorders is roughly parallel to the ammonium levels. With treatment, the fall in the NH_3 levels precedes clinical improvement. If the diagnosis remains uncertain, an intolerance to ammonium can be demonstrated by the administration of an oral dose of 6.0 g of NH_3Cl , which raises the blood NH_3 and sometimes produces mild symptoms of hepatic encephalopathy. In a normal person, this dosage does not alter the blood NH_3 concentrations.

Neuropathologic Changes The striking finding in patients who die in a state of hepatic coma is a diffuse increase in the number and size of the protoplasmic astrocytes in the deep layers of the cerebral cortex, lenticular nuclei, thalamus, substantia nigra, cerebellar cortex, and red, dentate, and pontine nuclei, with little or no visible alteration in the nerve cells or other parenchymal elements. With periodic acid–Schiff (PAS) staining, the astrocytes are seen to contain characteristic glycogen inclusions. These abnormal glial cells are generally referred to as Alzheimer type II astrocytes, having been described originally in 1912 by von Hosslin and Alzheimer in a patient with Westphal–Strümpell pseudosclerosis (familial hepatolenticular degeneration, or Wilson disease). These astrocytes have been studied electron microscopically in rats with surgically created portocaval shunts ([Cavanagh; Norenberg](#)); the astrocytes showed a number of striking abnormalities—swelling of their terminal processes, cytoplasmic vacuolation (distended sacs of rough endoplasmic reticulum), formation of folds in the basement membrane around capillaries, diminution in glycogen, and an increase in the number of mitochondria and in enzymes that catabolize ammonia. Also, some degeneration in myelinated nerve fibers in the neuropil and increase in the cytoplasm of oligodendrocytes were seen. In chronic cases, we have found neuronal loss in the deep layers of the cerebral and cerebellar cortex and in the lenticular nuclei as well as a vacuolization of tissue (possibly astrocyte vacuolation) resembling the lesions of Wilson disease.

The ubiquitous astrocytic alterations occur to some degree in all patients who die of progressive liver failure, and the degree of this glial abnormality corresponds roughly to the intensity and duration of the neurologic disorder. Presumably the astrocytic changes affect the synaptic activities of the neurons. The clinical and EEG features of hepatic encephalopathy as well as the astrocytic hyperplasia, though highly characteristic, are not specific features of this metabolic disorder. Nevertheless, taken together in a setting of liver failure, these manifestations constitute a distinctive clinicopathologic entity.

Pathogenesis of Hepatic Encephalopathy The most plausible hypothesis relates hepatic coma to an abnormality of nitrogen metabolism, wherein ammonia (NH_3), which is formed in the bowel by the action of urease-containing organisms on dietary protein, is carried to the liver in the portal circulation but fails to be converted into urea, because of either hepatocellular disease, portal-systemic shunting of blood, or both. As a result, excess amounts of NH_3 reach the systemic circulation, where they interfere with cerebral metabolism in a way that is not yet fully understood. Certainly the ammonia theory best explains the basic neuropathologic change. Norenberg has proposed that the hypertrophy of the astrocytic cytoplasm and proliferation of the mitochondria and endoplasmic reticulum, as well as the increase in the astroglial glutamic dehydrogenase activity, reflect the heightened metabolic activity associated with ammonia detoxification. Removal of brain ammonia depends upon the formation of glutamine, a reaction that is catalyzed by the ATP-dependent enzyme glutamine synthetase, which is localized in the astrocytes. It has been shown in experimental animals that hyperammonemia leads to a depletion of ATP in midbrain reticular nuclei. Whether this is the primary cause of coma has not been resolved.

Numerous alternative theories have been suggested. One is that CNS function in cirrhotic patients is impaired by phenols or short-chain fatty acids (from the diet or from bacterial metabolism of carbohydrate). Another suggestion is that biogenic amines (e.g., octopamine), which arise in the gut and bypass the liver, act as false neurotransmitters, displacing the putative transmitters norepinephrine and dopamine ([Fischer and Baldessarini](#)). Zieve has presented evidence that mercaptans (methanethiol, methionine), which are also generated in the gastrointestinal tract and removed by the liver, act in conjunction with NH_3 to produce hepatic encephalopathy. This theory and others have been the subject of reviews by Butterworth and coworkers, by Zieve, by Rothstein and Herlong, and by Jones and Basile, to which the reader is referred for detailed information.

For some time, it has been known that hepatic encephalopathy is associated with increased activity of the inhibitory transmitter GABA. It is also known that increased GABAergic neurotransmission may result from substances that inhibit the binding of endogenous benzodiazepines to their receptors ([Basile et al](#)), and these antagonists have some clinical effect (transient awakening) in patients with hepatic encephalopathy. The actions of benzodiazepines are mediated by these receptors—hence the designation *GABA-benzodiazepine theory*. The practicality of using benzodiazepine receptor antagonists (e.g., flumazenil) in the treatment of hepatic encephalopathy remains to be determined (see [Mullen](#)).

Until recently, the ammonia and the GABAergic-benzodiazepine hypotheses of the pathogenesis of hepatic encephalopathy have appeared to be unrelated and even mutually exclusive. However, there is a growing body of evidence (recently reviewed by [Jones and Basile](#)) that ammonia, even in the modestly elevated concentrations that occur in liver failure, probably enhances GABAergic neurotransmission—a concept that may unify the two hypotheses.

Also in recent years, manganese has emerged as a potential neurotoxin in the pathogenesis of hepatic encephalopathy ([Kreiger et al](#); [Pomier-Layrargues et al](#)). In patients with chronic liver diseases and with spontaneous or surgically induced portal-systemic shunts, manganese accumulates in the serum and in the brain, more specifically in the pallidum. This accumulation is readily discernible as a pallidal signal hyperintensity on T1-weighted MRI. Following liver transplantation, there is

normalization of the MRI changes and the associated extrapyramidal symptoms. The effects of manganese chelation on such patients have not been studied and the possible mechanisms of accumulated manganese in the pathogenesis of hepatic encephalopathy are not known.

Treatment Despite the incompleteness of our understanding of the role of disordered ammonium metabolism in the genesis of hepatic coma, an awareness of this relationship has provided the few effective means of treating this disorder: restriction of dietary protein; reducing bowel flora by oral administration of neomycin or kanamycin, which suppresses the urease-producing organisms in the bowel; and the use of enemas. The mainstay of treatment has been the use of lactulose, an inert sugar that acidifies the colonic contents and greatly reduces bacterial activity. The sustained use of oral neomycin carries a risk of renal damage and ototoxicity and has therefore been relegated to a second line of therapy. The salutary effects of these therapeutic measures, the common attribute of which is the lowering of the blood NH_3 , lend strong support to the theory of ammonia intoxication. Ultimately, in cases of intractable liver failure, transplantation becomes a treatment of last resort.

Other methods of treatment, the value of which still remains to be established, include the use of bromocriptine, flumazenil, and keto-analogues of essential amino acids. Theoretically, the keto-analogues should provide a nitrogen-free source of essential amino acids ([Maddrey et al](#)), and bromocriptine, a dopamine agonist, should enhance dopaminergic transmission ([Morgan et al](#)). Administration of branched-chain amino acids may result in considerable improvement in mental status, but their effects have been variable and associated with an increased mortality ([Naylor et al](#)).

Fulminant Hepatic Failure and Cerebral Edema In *acute hepatitis*, confusional, delirious, and comatose states also occur, but their mechanisms are still unknown. Blood NH_3 may be elevated, but usually not to a degree that would be expected to affect the CNS. Severe acute hepatic failure may cause hypoglycemia, which contributes to the encephalopathy and often presages a fatal outcome.

Cerebral edema is a prominent finding in cases of fulminant hepatic failure from any cause and is the main cause of death in patients awaiting liver transplantation. The cerebral edema that occurs in these circumstances appears to be related to the rapidity of rise of blood ammonia, but it probably depends as well on additional metabolic derangements that complicate acute liver failure. The combination of rapidly evolving hepatic failure and massive cerebral edema is similar to that observed in the Reye syndrome.

CT scanning is an effective means of detecting cerebral edema in patients with fulminant hepatic failure, and the degree of cerebral swelling is roughly proportional to the severity of encephalopathy ([Wijdicks et al](#)). Since patients with fulminant hepatic failure can survive liver transplantation with few or no neurologic deficits, it is important to recognize cerebral edema early, before the stages of stupor and coma and greatly increased intracranial pressure have been reached. Short of transplantation, death in these cases may sometimes be prevented by monitoring the intracranial pressure (as outlined by [Lidofsky et al](#)) and by the use of osmotic diuretics and hyperventilation, as detailed in [Chap. 30](#). However, some survivors may be left with cerebral damage from raised intracranial pressure.

Reye Syndrome (Reye-Johnson Syndrome) As indicated above, this is a special type of nonicteric hepatic encephalopathy occurring in children and adolescents and characterized by acute brain swelling in association with fatty infiltration of the viscera, particularly of the liver. Although individual cases of this disorder had been described for many years, its recognition as a clinical-pathologic entity dates from 1963, when a large series was reported from Australia by Reye and colleagues and from the United States by Johnson and coworkers. The disorder tends to occur in outbreaks (286 cases were reported to the Centers for Disease Control during a 4-month period in 1974). Mainly, these outbreaks were observed in association with influenza B virus and varicella infections, but a variety of other viral infections have been implicated (influenza A, echovirus, reovirus, rubella, rubeola, herpes simplex, Epstein-Barr virus). In addition, the toxic or adjuvant effects of aspirin given during these infections seem to play a role in producing the disease. Only occasional instances of the Reye syndrome are observed now that the association with aspirin administration has become widely known and its use in children with the above infections has been interdicted.

Most patients are children, boys and girls being equally affected, but rare instances have been observed in infants ([Huttenlocher and Trauner](#)) and in young adults. In most cases the encephalopathy is preceded for several days to a week by fever, symptoms of upper respiratory infection, and protracted vomiting. These symptoms are followed by the rapid evolution of stupor and coma, associated in many cases with focal and generalized seizures, signs of sympathetic overactivity (tachypnea, tachycardia, mydriasis), decorticate and decerebrate rigidity, and loss of pupillary, corneal, and vestibulo-ocular reflexes. In infants, respiratory distress, tachypnea, and apnea are the most prominent features. The liver may be greatly enlarged, often extending to the pelvis and providing an important diagnostic clue as to the cause of the cerebral changes. Initially there is a metabolic acidosis, followed by a respiratory alkalosis (rising arterial pH and falling P_{CO_2}). The CSF is usually under increased pressure and is acellular; glucose values may be low, reflecting the hypoglycemia. The serum glutamic-oxaloacetic transaminase (SGOT), prothrombin time, and blood ammonia are increased, sometimes to an extreme degree. The EEG is characterized by diffuse arrhythmic delta activity, progressing to electrocerebral silence in patients who fail to survive.

The major *pathologic findings* are cerebral edema, often with cerebellar herniation, and infiltration of hepatocytes with fine droplets of fat (mainly triglycerides); the renal tubules, myocardium, skeletal muscles, pancreas, and spleen are infiltrated to a lesser extent. There are no inflammatory lesions in the brain, liver, or other organs. There is not full agreement as to the pathogenesis of this disorder.

Prognosis and Treatment In a series of children with blood ammonia levels greater than 500 mg/dL who were treated during the years 1967 to 1974, Shaywitz and colleagues reported a mortality of 60 percent. Once the child became comatose, death was almost inevitable. In more recent years, early diagnosis (elevations of SGOT, prothrombin time, and serum NH_3) and initiation of treatment before the onset of coma have reduced the fatality rate to 5 to 10 percent. Treatment consists of the following measures: temperature control with a cooling blanket; nasotracheal intubation and controlled ventilation to maintain P_{CO_2} above 20 mmHg; intravenous glucose covered by insulin to maintain blood glucose at 150 to 200 mg/dL; administration of neomycin enemas and lactulose; control of intracranial pressure by means of continual monitoring and the use of hypertonic solutions (see [Chap. 30](#)); and the maintenance of fluid and electrolyte balance ([Trauner](#)). Upon recovery, cerebral function returns to normal unless there had been deep and prolonged coma or protracted elevation of intracranial pressure.

Uremic Encephalopathy

Episodic confusion and stupor and other neurologic symptoms may accompany any form of severe renal disease—acute or chronic. The cerebral symptoms attributable to uremia per se (first described by Addison in 1832) are best discerned in normotensive individuals in whom renal failure develops rapidly. Apathy, fatigue, inattentiveness, and irritability are usually the initial symptoms; later, there is confusion, disturbances of sensory perception, hallucinations, dysarthria, and asterixis. Sometimes this takes the form of a toxic psychosis, with hallucinations, delusions, insomnia, or catatonia ([Marshall](#)). Characteristically these symptoms fluctuate from day to day or even from hour to hour. In some patients, especially in those who become anuric, symptoms may come on rather abruptly and progress rapidly to a state of stupor and coma. In others, in whom uremia develops more gradually, mild visual hallucinations and a disorder of attention may persist for several weeks in relatively pure form. The EEG becomes diffusely slow and may remain so for several weeks after the institution of dialysis. The CSF pressure is normal and the protein is not elevated unless there is a uremic or diabetic neuropathy. In several reports, meningismus and a low-grade mononuclear pleocytosis is mentioned, but we have not found this.

In acute renal failure, clouding of the sensorium is practically always associated with a variety of motor phenomena, which usually occur early in the course of the encephalopathy, sometimes when the patient is still mentally clear. The patient begins to twitch and jerk and may convulse. The twitches involve parts of muscles, whole muscles, or limbs and are lightning-quick, arrhythmic, and asynchronous on the two sides of the body; they are incessant during both wakefulness and sleep. At times the movements resemble those of chorea or an arrhythmic tremor, and asterixis is readily evoked. The motor phenomena are often difficult to classify. The authors prefer to describe the condition as the *uremic twitch-convulsive syndrome*.

Because of the similarity of this syndrome to tetany, measurement should be made of serum calcium and magnesium—and, of course, hypocalcemia and hypomagnesemia do occur in uremia. But often the values for these ions are normal or near normal, and the administration of calcium and magnesium salts has little effect. The resemblance of uremic encephalopathy to hepatic and other metabolic encephalopathies has been stressed by Raskin and Fishman, yet we are more impressed with differences than with similarities. We have observed the twitch-convulsive syndrome in association with a variety of diseases such as widespread neoplasia, delirium tremens, diabetes with necrotizing pyelonephritis, and lupus erythematosus, in which the blood urea nitrogen was only modestly elevated; but always the factor of renal failure was ultimately discovered.

As the uremia worsens, the patient lapses into a quiet coma. Unless the accompanying metabolic acidosis is corrected, Kussmaul breathing appears and gives way to Cheyne-Stokes breathing and death.

It is important to keep in mind that encephalopathy and coma in the patient with renal failure may be due to disorders other than uremia itself. The altered excretion of drugs leads to their accumulation, sometimes evoking excessive sedation even though serum concentrations are normal. Subdural and intracerebral hemorrhages

may complicate uremia because of clotting defects and hypertension, and chronically azotemic patients are prone to infections, including meningitis.

Since uremia is so frequently associated with hypertension, a major problem also arises in distinguishing the cerebral effects of uremia from those of severe and accelerated hypertension. Volhard was the first to make this distinction; he introduced the term *pseudouremia* to designate the cerebral effects of malignant hypertension and to separate them from true uremia. The term *hypertensive encephalopathy*, by which pseudouremia is now known, was first used by Oppenheimer and Fishberg. The clinical picture of the latter disorder and its pathophysiology are discussed on page 903.

Opinions vary as to the biochemical basis of uremic encephalopathy and the twitch-convulsive syndrome. Restoration of renal function completely corrects the neurologic syndrome, attesting to a functional disorder of subcellular type. Whether caused by the retention of organic acids, elevation of phosphate in the CSF (claimed by [Harrison et al](#)), or the action of urea or other toxins has never been settled. The data supporting the causative role of urea are ambiguous, as they are for other endogenous putative agents (see [Bolton and Young](#) and the review by [Burn and Bates](#)). However, it can be stated that urea itself is not the sole inductive agent, since its infusion does not produce the syndrome in man or animals.

It would appear that every level of the CNS is affected, from spinal cord to cerebrum. The authors have been unable to detect cellular changes in the brain or spinal cord other than a mild hyperplasia of protoplasmic astrocytes in some cases, but never of the degree observed in hepatic encephalopathy. Cerebral edema is notably absent. In fact, CT scans and MRI regularly show an element of cerebral shrinkage, probably on the basis of hyperosmolality. A peripheral neuropathy is also a common complication of uremia and is considered in [Chap. 46](#).

In the *treatment* of uremic encephalopathy, the nature of the renal disease assumes paramount importance; if it is irreversible and progressive, the prognosis is poor without dialysis or renal transplantation. Improvement of encephalopathic symptoms may not be evident for a day or two after institution of dialysis. Convulsions, which occur in about one-third of cases, often preterminally, may respond to relatively low plasma concentrations of anticonvulsants, the reason being that serum albumin is depressed in uremia, increasing the unbound, therapeutically active portion. If there are severe associated metabolic disturbances, such as hyponatremia, the seizures may be difficult to control. One must be cautious in prescribing any of a large number of drugs in the face of renal failure, for inordinately high, toxic blood levels may result. Examples are aminoglycoside antibiotics (vestibular damage); furosemide (cochlear damage); and nitrofurantoin, isoniazid, and hydralazine (peripheral nerve damage).

Dialysis “Disequilibrium Syndrome” This term refers to a group of symptoms that may occur during and following hemodialysis or peritoneal dialysis in association with some degree of cerebral edema. The symptoms include headaches, nausea, muscular cramps, nervous irritability, agitation, drowsiness, and convulsions. The headache, which may be bilateral and throbbing or resemble common migraine, develops in approximately 70 percent of patients, while the other symptoms are observed in 5 to 10 percent, usually in those undergoing rapid dialysis or in the early stages of a dialysis program. The symptoms tend to occur in the third or fourth hour of dialysis and last for several hours. Sometimes they appear 8 to 48 h after the completion of dialysis. Originally these symptoms were attributed to the rapid lowering of serum urea, leaving the brain with a higher concentration of urea than the serum and resulting in a shift of water into the brain to equalize the osmotic gradient (*reverse urea syndrome*). Now it is believed that the shift of water into the brain is akin to water intoxication and is due to the inappropriate secretion of antidiuretic hormone.

The symptoms of subdural hematoma, which in some series have occurred in 3 to 4 percent of patients undergoing dialysis, may be mistakenly attributed to the disequilibrium syndrome.

Dialysis Encephalopathy (Dialysis Dementia) This is a subacutely progressive syndrome, now virtually extinct, that complicated chronic hemodialysis. Characteristically the condition begins with a hesitant, stuttering dysarthria, dysphasia, and sometimes apraxia of speech, to which are added facial and then generalized myoclonus, focal and generalized seizures, personality and behavioral changes, and intellectual decline. The EEG is invariably abnormal, taking the form of paroxysmal and sometimes periodic sharp-wave or spike-and-wave activity (up to 500 mV and lasting 1 to 20 s) intermixed with abundant theta and delta activity. The CSF is normal except, occasionally, for increased protein.

At first the myoclonus and speech disorders are intermittent, occurring during or immediately after dialysis and lasting for only a few hours, but gradually they become more persistent and eventually permanent. Once established, the syndrome is usually steadily progressive over a 1- to 15-month period (average survival of 6 months in the 42 cases analyzed by Lederman and Henry).

The neuropathologic changes are subtle and consist of a mild degree of microcavitation of the superficial layers of the cerebral cortex. Although the changes are diffuse, they have been found, in one study, to be more severe in the left (dominant) hemisphere than in the right and more severe in the left frontotemporal operculum than in the surrounding cortex ([Winkelman and Ricanati](#)). The disproportionate affection of the left frontotemporal opercular cortex would explain the distinctive disorder of speech and language.

The current view of the pathogenesis of dialysis encephalopathy is that it represented a form of aluminum intoxication ([Alfrey et al](#)), the aluminum being derived from the dialysate or from orally administered aluminum gels. In recent years, this disorder has disappeared, the result, no doubt, of the universal practice of purifying the water used in dialysis and thereby removing aluminum from the dialysate. The subject has been reviewed by Parkinson and coworkers.

Complications of Renal Transplantation The risk, in immunosuppressed persons, of developing a primary lymphoma of the brain or progressive multifocal leukoencephalopathy has already been mentioned (pages 695 and 812). A different encephalopathy that is marked by widespread edema of the cerebral white matter, evident on the MRI and predominantly occipital, occurs after the administration of cyclosporine and other immunosuppressants. The pattern on MRI is not specific, being seen also in patients with hypertensive encephalopathy and other conditions. Systemic fungal infections are found at autopsy in about 45 percent of patients who have had renal transplants and long periods of immunosuppressive treatment; in about one-third of these patients, the CNS is involved. *Cryptococcus*, *Listeria*, *Aspergillus*, *Candida*, *Nocardia*, and *Histoplasma* are the usual organisms. Other CNS infections that have complicated transplantation are toxoplasmosis and cytomegalic inclusion disease.

In some nutritionally depleted uremic patients who are subjected to treatment that involves major shifts of plasma water and electrolytes, diseases unrelated to uremia may develop. In our necropsy material, we have found examples of Wernicke-Korsakoff disease and central pontine myelinolysis. A bleeding diathesis may result in subdural or cerebral hemorrhage.

Encephalopathy Associated with Sepsis and Burns

Bolton and Young have drawn attention to the frequent occurrence, in severely septic patients, of a drowsy or confusional state that is reversible but is not explained by hepatic, pulmonary, or renal failure, electrolyte imbalance, hypotension, drug intoxication, or a primary lesion of the brain. According to their surveys, 70 percent of patients become disoriented and confused within hours of the onset of severe systemic infection; in a few cases, this state may progress to stupor and coma. Notably there are no signs of asterixis, myoclonus, or focal cerebral disorder, but paratonia is common, as is the later development of a polyneuropathy.

The encephalopathic state that occurs with severe systemic infection may also occur independently of sepsis, as a component of a syndrome of multiple organ failure and as a complication of widespread cutaneous burns ([Aikawa et al](#)).

It has been useful, in clinical work, to distinguish these encephalopathies of infection and multiorgan failure from those due to isolated hepatic or renal disease. The lack of a biochemical marker and the confounding effects of hypotension during sepsis (septic shock) leave doubt as to pathogenesis. Altered phenylalanine metabolism and circulating cytokines have been proposed as causes, without firm evidence. Of interest in two of our fatal cases was the presence of *brain purpura*, but this has otherwise been an infrequent finding. The white matter of the cerebrum and cerebellum was speckled with myriads of pericapillary hemorrhages and zones of pericapillary necrosis. This pathologic reaction is nonspecific, having also been seen in some of our cases (10 in all) of viral pneumonia, heart failure with morphine overdose, and arsenical intoxication.

Disorders of Sodium, Potassium, and Water Balance

Drowsiness, confusion, stupor, and coma, in conjunction with seizures and sometimes with other neurologic deficits, may have as their basis a more or less pure abnormality of electrolyte or water balance. Only brief reference is made to some of these—such as hypocalcemia, hypercalcemia, hypophosphatemia, and

hypomagnesemia—since they are considered in other parts of the text.

Hyponatremia Among the many causes of hyponatremia, the *syndrome of inappropriate antidiuretic hormone secretion (SIADH)* is of special importance, since it may complicate neurologic diseases of many types—head trauma, bacterial meningitis and encephalitis, cerebral infarction, subarachnoid hemorrhage, neoplasm, and Guillain-Barré disease. The diagnosis of SIADH should be suspected in any critically ill neurologic or neurosurgical patient who excretes urine that is hypertonic relative to the plasma. As the hyponatremia develops, there is a decrease in alertness, which progresses through stages of confusion to coma, often with convulsions. *As with many other metabolic derangements, the severity of the clinical effects is related to the rapidity of decline in serum Na.* Lack of recognition of this state may allow the serum Na to fall to dangerously low levels, 100 meq/L or lower. One's first impulse is to administer NaCl intravenously, but this must be done cautiously, because in most of these patients the intravascular volume is already expanded and there is a risk of congestive heart failure. Most cases respond to the restriction of fluid intake—to 500 mL per 24 h if the serum Na is less than 120 meq/L and to 1000 mL per 24 h if less than 130 meq/L. Even when the Na reaches 130 meq/L, the fluid intake should not exceed 1500 mL per 24 h. In extreme cases of hyponatremia with stupor or seizures, infusion of NaCl is necessary. The amount of NaCl to be infused can be calculated from the current and the target levels of serum Na by assuming that the infused sodium load is distributed throughout the total body water content ($0.6 \times \text{weight in kg}$):

$$\frac{[\text{Target Na} - \text{starting Na}] \times 0.6 \times \text{weight (kg)}}{= \text{desired infused Na load (meq)}}$$

The desired volume of normal saline can then be calculated by keeping in mind that its sodium concentration is 154 meq/L, and that of 3 percent (hypertonic) saline is 462 meq/L. If hypertonic saline is administered, it is usually necessary to simultaneously reduce intravascular volume with furosemide, beginning with a dose of 0.5 mg/kg intravenously, and to increase the dosage until a diuresis is obtained. Guidelines for the rapidity of correction of Na are elaborated further on in relation to central pontine myelinolysis (no more than 10 mmol/L in the first 24 h). Although the syndrome of SIADH is self-limiting, it may continue for weeks or months, depending on the type of associated brain disease.

It must be emphasized that not all patients with intracranial disorders who show hyponatremia and natriuresis have SIADH. In fact, in many of such patients, renal loss of salt is the cause of hyponatremia and, in contrast to SIADH, results in decreased blood volume. The process has been termed “cerebral salt wasting” ([Nelson et al](#)). Sodium loss in these circumstances is attributable to the production by the heart or brain of a potent polypeptide, atrial natriuretic factor. As discussed in [Chap. 34](#), under “Subarachnoid Hemorrhage,” the distinction between SIADH and cerebral salt wasting is of more than theoretical importance, insofar as fluid restriction to correct hyponatremia may be dangerous in patients with salt wasting, particularly in those with vasospasm after ruptured intracranial aneurysms.

Arieff has emphasized the hazards of *postoperative hyponatremia*. He has reported a series of 15 patients, all of them women, in whom *severe hyponatremia* followed elective surgery. About 48 h after these patients had recovered from anesthesia, their serum Na fell to an average level of 108 meq/L; the urinary sodium was 68 mmol/L, and the urinary osmolality was 501 mosmol/kg. At this point, generalized seizures occurred, followed by respiratory arrest, requiring intubation. Of the 15 women, 5 died; there were no diagnostic pathologic findings, and no lesions of central pontine myelinolysis (see below) were found. Seven patients, whose serum Na was corrected slowly, improved over a period of several days but then developed a rapidly progressive diminution in alertness and increasing nausea, headache, and obtundation, followed by a recurrence of seizures and coma. These patients survived in a persistent vegetative state. We find the syndrome difficult to interpret. The initial hyponatremia was probably the result of SIADH. What happened later could have been the consequence of immediate and delayed hypoxia, but this is speculative.

An important consideration in the management of severe hyponatremia and hyperosmolality is *the rapidity with which these abnormalities are corrected and the danger of provoking central pontine myelinolysis (CPM)* and related brainstem, cerebellar, and cerebral lesions (extrapontine myelinolysis). These issues are considered below, in the section on CPM.

Hypernatremia Severe hypernatremia (Na >155 meq/L) and dehydration are observed in diabetes insipidus, the neurologic causes of which include head trauma with damage to the pituitary stalk ([Chap. 27](#)), nonketotic diabetic coma, protracted diarrhea in infants, and the deprivation of fluid intake in the stuporous patient. The last condition is usually associated with a brain lesion that impairs consciousness. Exceptionally, in patients with chronic hydrocephalus, the hypothalamic thirst center is rendered inactive, and severe hypernatremia, stupor, and coma may follow a failure to drink. In hypernatremia from any cause, the brain volume is manifestly reduced in CT scans. Retraction of the cerebral cortex from the dura has been known to rupture a bridging vein and cause a subdural hematoma.

As is true for hyponatremia, the degree of CNS disturbance in hypernatremia is generally related to the rate at which the serum Na rises. Slowly rising values, to levels as high as 170 meq/L, are often well tolerated. Rapid elevations shrink the brain, especially in infants. Extremely high levels cause impairment of consciousness with asterixis, myoclonus, seizures, and choreiform movements. In addition, muscular weakness, rhabdomyolysis, and myoglobinuria have been reported.

It is to be noted that hyponatremia is usually accompanied by hypo-osmolality of the serum, and hypernatremia by hyperosmolality. However, there is no strict correlation between the degree of hypo- or hyperosmolality and neurologic dysfunction. Instead, the rapidity of change, as already emphasized, plays a major role. In hyponatremia plus hypo-osmolality, Fishman finds an increase in intracellular water and a diminution in intracellular K; but in our view it is the dehydration that is more critical and coincides with the neuronal derangement. In hypernatremia plus hyperosmolality, the neurons do not lose water as much as do other cells, a compensatory reaction that Fishman attributes to the presence of “idiogenic osmoles”—probably glucose, glucose metabolites, and amino acids. The impairment of neuronal function in this state is not understood. Theoretically one would expect neuronal shrinkage and possibly alteration of the synaptic surface of the cell.

Hypo- and Hyperkalemia The main clinical effect of *hypokalemia* (K, 2.0 meq/L or less) is generalized muscular weakness (see [Chap. 48](#)). A confusional state may also be added but is infrequent. Both conditions are readily corrected by adding K to intravenous fluid and infusing it at no more than 4 to 6 meq/h. *Hyperkalemia* (above 7 meq/L) also may manifest itself by generalized muscle weakness, although the main effects are changes in the electrocardiogram (ECG), possibly leading to cardiac arrest.

Other Metabolic Encephalopathies Limitation of space permits only brief reference to other metabolic disturbances that may present as episodic confusion, stupor, or coma. The most important members of this group are summarized below.

Hypercalcemia This is defined as an elevation of the serum calcium concentration above 10.5 mg/dL. If the serum protein content is normal, Ca levels greater than 12 mg/dL are required to produce neurologic symptoms. However, with low serum albumin levels, an increased proportion of the serum Ca is in the unbound or ionized form (upon which the clinical effects depend), and symptoms may occur with serum Ca levels as low as 10 mg/dL.

In young persons, the most common cause of hypercalcemia is hyperparathyroidism (either primary or secondary); in older persons, osteolytic bone tumors, particularly metastatic carcinoma and multiple myeloma, are often causative. Less common causes are vitamin D intoxication, prolonged immobilization, hyperthyroidism, sarcoidosis, and decreased calcium excretion (renal failure).

Anorexia, nausea and vomiting, fatigue, and headache are usually the *initial symptoms*, followed by confusion (rarely a delirium) and drowsiness, progressing to stupor or coma in untreated patients. Diffuse myoclonus and rigidity occur occasionally, as do elevations of spinal fluid protein (up to 175 mg/100 mL). Convulsions occur uncommonly.

Hypocalcemia The usual manifestations of *hypocalcemia* are tetany and seizures. With severe and persistent hypocalcemia, altered mental status in the form of depression, confusion, dementia, or personality change can occur. Even coma may result, in which case there may be papilledema due to increased intracranial pressure. Aside from the raised pressure, the CSF shows no consistent abnormality. This increase in intracranial pressure may be manifest by headache and papilledema without altered mentation. Hypoparathyroidism is discussed further on.

Metabolic acidosis from any cause produces a typical syndrome of drowsiness, stupor, and coma, with dry skin and Kussmaul breathing. The CNS depression does not correlate with the concentration of ketones. Probably there are associated effects on neurotransmitters, consequent to the increase in osmolality and release of intracellular calcium.

In infants and children, acidosis may occur in the course of hyperammonemia, isovaleric acidemia, maple syrup urine disease, lactic and glutaric acidemia, hyperglycinemia, and other disorders, which are described in detail in [Chap. 37](#). High-voltage slow activity predominates in the EEG, and correction of the acidosis or

elevated ammonia level restores CNS function to normal provided that coma was not prolonged or complicated by hypoxia or hypotension. In uncomplicated acidotic coma, we have observed no recognizable neuropathologic change by light microscopy.

Encephalopathy due to *Addison disease* (adrenal insufficiency) may be attended by episodic confusion, stupor, or coma without special identifying features; it is usually precipitated in the addisonian patient by infection or surgical stress. Hemorrhagic destruction of the adrenals is another cause. Hypotension and diminished cerebral circulation and hypoglycemia are the most readily recognized metabolic abnormalities; measures that correct these conditions reverse the adrenal crisis in some instances.

Myxedema is well known to cause a mental dullness, drowsiness, and stupor. We have encountered several instances of an encephalopathy with myoclonus in patients with Hashimoto thyroiditis; some of these patients had nearly normal thyroid function studies, but they had high titers of antithyroglobulin antibodies; the encephalopathy in the latter case is thought to be on an autoimmune basis. These are discussed in a later part of the chapter.

The various neurologic syndrome that are consequent upon electrolytic disorders have been reviewed by Laureno.

Central Pontine Myelinolysis

In 1950, Adams and Victor observed a rapidly evolving quadriplegia and pseudobulbar palsy in a young alcoholic man who had entered the hospital 10 days earlier with symptoms of alcohol withdrawal. Postmortem examination several weeks later disclosed a large, symmetrical, essentially demyelinating lesion occupying the greater part of the basis pontis. Over the next 5 years, three additional cases (two alcoholic patients and one with scleroderma) were studied clinically and pathologically, and in 1959 these four cases were reported by [Adams et al](#) under the heading of *central pontine myelinolysis* (CPM). This term was chosen because it denotes both the specific anatomic localization of the disease and its essential pathologic attribute: the remarkably unsystematic dissolution of the sheaths of medullated fibers. Once attention was focused on this distinctive lesion, many other reports appeared. The exact incidence of this disease is not known, but in a series of 3548 consecutive autopsies in adults, the typical lesion was found in 9 cases, or 0.25 percent ([Victor and Laureno](#)).

Pathologic Features One is compelled to define this disease in terms of its pathologic anatomy, because this stands as its most certain feature. Transverse sectioning of the fixed brainstem discloses a grayish discoloration and fine granularity in the center of the basis pontis. The lesion may be only a few millimeters in diameter, or it may occupy almost the entire basis pontis. There is always a rim of intact myelin between the lesion and the surface of the pons. Posteriorly it may reach and involve the medial lemnisci and, in the most advanced cases, other tegmental structures as well. Very rarely, the lesion encroaches on the midbrain, but inferiorly it does not extend as far as the medulla. Exceptionally the extensive pontine lesions may be associated with identical myelinolytic foci symmetrically distributed in the thalamus, subthalamic nucleus, striatum, internal capsule, amygdaloid nuclei, lateral geniculate body, white matter of the cerebellar folia, and deep layers of the cerebral cortex and subjacent white matter (“extrapontine myelinolysis”; Wright et al).

Microscopically, the fundamental abnormality consists of destruction of the medullated sheaths throughout the lesion, with relative sparing of the axis cylinders and intactness of the nerve cells of the pontine nuclei. These changes always begin and are most severe in the geometric center of the pons, where they may proceed to frank necrosis of tissue. Reactive phagocytes and glial cells are in evidence throughout the demyelinating focus, but no oligodendrocytes are seen. Signs of inflammation are conspicuously absent.

This constellation of pathologic findings provides easy differentiation of the lesion from infarction and the inflammatory demyelinations of multiple sclerosis and postinfectious encephalomyelitis. Microscopically, the lesion resembles that of Marchiafava-Bignami disease ([Chap. 41](#)), with which it is rarely associated. Wernicke disease is not infrequently associated with CPM, but the lesions bear no resemblance to one another in terms of topography and histology.

Clinical Features Central pontine myelinolysis occurs only sporadically, with no hint of a genetic factor. The two sexes are affected equally, and the patients do not fall into any one age period. Whereas the cases first reported had occurred in adults, there are now many reports of the disease in children, particularly in those with severe burns ([McKee et al](#)).

The outstanding clinical characteristic of CPM is its invariable association with some other serious, often life-threatening disease. In more than half the cases, it has appeared in the late stages of chronic alcoholism, often in association with Wernicke disease and polyneuropathy. Among the other medical conditions and diseases with which CPM has been conjoined are chronic renal failure being treated with dialysis, hepatic failure, advanced lymphoma, carcinoma, cachexia from a variety of other causes, severe bacterial infections, dehydration and electrolyte disturbances, acute hemorrhagic pancreatitis, and pellagra.

In many patients with CPM there are no symptoms or signs that betray the pontine lesion, presumably because it is so small, extending only 2 to 3 mm on either side of the median raphe and involving only a small portion of the corticopontine or pontocerebellar fibers. In others, the presence of CPM is obscured by coma from a metabolic or other associated disease. Probably only a minority of cases, exemplified by the first patient whom we observed, are recognized during life. In this patient, a serious alcoholic with delirium tremens and pneumonia, there evolved, over a period of several days, a flaccid paralysis of all four limbs and an inability to chew, swallow, or speak (thus simulating occlusion of the basilar artery). Pupillary reflexes, movements of the eyes and lids, corneal reflexes, and facial sensation were spared. In some instances, however, conjugate eye movements are limited, and there may be nystagmus. With survival for several days, the tendon reflexes become more active, followed by spasticity and extensor posturing of the limbs on painful stimulation. Some patients are left in a state of mutism and paralysis with relative intactness of sensation and comprehension, i.e., the “locked-in syndrome.”

The capacity of CT scanning but especially MRI to visualize the pontine lesion has greatly increased the frequency of premortem diagnoses. The MRI discloses a characteristic “bat wing” lesion of the basis pontis in some cases ([Fig. 40-2](#)), although this change may become evident only several days after the onset of symptoms. Brainstem auditory evoked responses also disclose the lesions that encroach upon the pontine tegmentum.

Figure 40-2 T2-weighted MR image showing the typical lesion of central pontine myelinolysis in an alcoholic patient.

Variants of this syndrome are being encountered with increasing frequency. Two of our elderly patients, with confusion and stupor—but without signs of corticospinal or pseudobulbar palsy—recovered; however, they were left with a severe dysarthria and cerebellar ataxia lasting many months. By CT and MRI, no lesions were observed in the tegmentum of the brainstem and cerebellum. After 6 months, these patients' nervous system function was essentially normal; originally both had serum Na levels of 99 meq/L, but information about the rate of restoration of serum Na was not available. Another of our patients developed a typical locked-in syndrome after the rapid correction of a serum sodium of 104 meq/L. He showed large symmetrical lesions of the frontal cortex and underlying white matter but no pontine lesion (by MRI).

Brainstem infarction due to basilar artery occlusion may be a source of confusion to the clinician. Sudden onset or step-like progression of the clinical state, asymmetry of long tract signs, and more extensive involvement of tegmental structures of the pons as well as the midbrain and thalamus are the distinguishing characteristics of vertebrobasilar thrombosis or embolism. Massive pontine demyelination in acute or chronic relapsing multiple sclerosis rarely produces a pure basis

pontis syndrome. Other features of this disease provide the clues to correct diagnosis.

Etiology and Pathogenesis Nutritional deficiency is a commonly invoked cause of CPM, because it is observed so frequently in chronic wasting diseases and particularly in malnourished alcoholics, often in association with Wernicke disease. Nevertheless, there are cases in which a nutritional factor cannot be incriminated. As mentioned in the section on hyponatremia, the rapid correction of the serum sodium to normal or higher than normal levels plays an important role in the genesis of CPM. Significant hyponatremia, always less than 130 meq/L and usually much less, has been present in all our patients and in all the patients reported by Burcar and colleagues and by Karp and Laureno. The importance of serum sodium in the pathogenesis of this disease was demonstrated experimentally by Laureno. Dogs were made severely hyponatremic (100 to 115 meq/L) by repeated injections of vasopressin and intraperitoneal infusions of water. The hyponatremia and profound weakness were corrected rapidly by infusion of hypertonic (3%) saline, following which the dogs developed a rigid quadriplegia and showed, at autopsy, pontine and extrapontine lesions that were indistinguishable in their distribution and histologic features from those of the human disease. Hyponatremia alone or slowly corrected hyponatremia (<15 meq/dL in the initial 24 h) did not produce the disease.

McKee and colleagues have adduced evidence that extreme serum hyperosmolality and not necessarily the rapid correction or overcorrection of hyponatremia is the important factor in the pathogenesis of CPM. They found the characteristic pontine and extrapontine lesions in 10 of 139 severely burned patients who were examined after death. Each of their patients with CPM had suffered a prolonged, nonterminal episode of severe serum hyperosmolality, which coincided temporally with the onset of the lesion, as judged by its histologic features. Hyponatremia was not present, and no other independent factors—such as hypernatremia, hyperglycemia, or azotemia—correlated with the development of CPM.

Therapeutic guidelines for the correction of hyponatremia are still being considered. Karp and Laureno, on the basis of their experience and that of Sterns et al, have suggested that the hyponatremia be corrected by no more than 10 meq/L in the initial 24 h and by no more than 21 meq/L in the initial 48 h.

At the present time all one can say is that specific regions or zones of the brain, most often the center of the basis pontis, have a special susceptibility to some acute metabolic fault (possibly rapid correction or overcorrection of hyponatremia, possibly hyperosmolality), analogous perhaps to the selective vulnerability of the corpus callosum and anterior commissure in Marchiafava-Bignami disease ([Chap. 41](#)).

METABOLIC DISEASES PRESENTING AS PROGRESSIVE EXTRAPYRAMIDAL SYNDROMES

These syndromes are usually of mixed type—i.e., they include a number of basal ganglionic and cerebellar symptoms in various combinations and may emerge as part of an acquired chronic hepatocerebral degeneration or chronic hypoparathyroidism or as sequels to kernicterus or hypoxic or hypoglycemic encephalopathy. The basal ganglionic-cerebellar symptoms that result from severe anoxia and hypoglycemia have been described in the preceding section and in [Chap. 4](#) and [Chap. 5](#). Kernicterus is considered on page 1085, with the neurologic diseases of infancy and childhood, and calcification of the basal ganglia and cerebellum (due to chronic parathyroid deficiency) on page 1032, with the inherited metabolic disorders, as well as further on in this chapter. It must be realized, however, that acquired hypoparathyroidism may also lead to calcification of the basal ganglia (see below, under “[Metabolic Diseases Presenting as Cerebellar Ataxia](#)”). We have observed choreiform movements in patients with hyperosmolar coma and with severe hyperthyroidism, ascribed by Weiner and Klawans to a disturbance of dopamine metabolism.

Chronic Acquired (Non-Wilsonian) Hepatocerebral Degeneration

Patients who survive an episode or several episodes of hepatic coma are sometimes left with residual neurologic abnormalities, such as tremor of the head or arms, asterixis, grimacing, choreic movements and twitching of the limbs, dysarthria, ataxia of gait, or impairment of intellectual function; these symptoms may worsen, with repeated attacks of stupor and coma. In a few patients with chronic liver disease, permanent neurologic abnormalities become manifest in the absence of discrete episodes of hepatic coma. In either event, patients with these abnormalities deteriorate neurologically over a period of years. Examination of the brains of such patients discloses foci of destruction of nerve cells and other parenchymal elements in addition to a widespread transformation of astrocytes—changes that are very much the same as those of Wilson disease.

Probably the first to describe the acquired type of hepatocerebral degeneration was van Woerkom (1914), whose report appeared only 2 years after Wilson's classic description of the familial form. A full account of the cases reported since that time as well as of our own extensive experience with this disorder is contained in the article by Victor, Adams, and Cole, listed in the References.

Clinical Features The first symptom may be a tremor of the outstretched arms, fleeting arrhythmic twitches of the face and limbs (resembling either myoclonus or chorea), or a mild unsteadiness of gait with action tremor. As the condition evolves over months or years, a rather characteristic dysarthria, ataxia, wide-based, unsteady gait, and choreoathetosis—mainly of the face, neck, and shoulders—are joined in a common syndrome. Mental function is slowly altered, taking the form of a simple dementia with a seeming lack of concern about the illness. A coarse, rhythmic tremor of the arms appearing with certain sustained postures, mild corticospinal tract signs, and diffuse EEG abnormalities complete the clinical picture. Other less frequent signs are muscular rigidity, grasp reflexes, tremor in repose, nystagmus, asterixis, and action or intention myoclonus. In essence, each of the neurologic abnormalities that are observed in patients with acute hepatic encephalopathy are also part of chronic hepatocerebral degeneration, the only difference being that the abnormalities are evanescent in the former and irreversible and progressive in the latter.

As a rule, all measurable hepatic functions are altered, but the chronic neurologic disorder correlates best with an elevation of serum ammonia (usually greater than 200 mg/dL). Unlike Wilson disease, where the cirrhosis usually remains occult for a long time, there is no question about its presence in the acquired syndrome; jaundice, ascites, and esophageal varices are manifest in most of the acquired cases. Wilson disease, which enters into the differential diagnosis, is usually not difficult to differentiate on clinical grounds, although the distinction in some cases requires the critical evidence of familial occurrence, Kayser-Fleischer rings (never found in the acquired type), and certain biochemical abnormalities (diminished serum ceruloplasmin, elevated serum copper, and urinary copper excretion—see page 1026).

Pathology The chronic cerebral symptoms, like the transient ones, may occur with all varieties of chronic liver disease. The cerebral lesion is localized more regularly in the cortex than is the case in Wilson disease. In some specimens an irregular gray line of necrosis or gliosis can be observed throughout both hemispheres, and the lenticular nuclei may appear shrunken and discolored. These lesions resemble hypoxic ones and may be concentrated in the vascular border zones, but they tend to spare the hippocampus, globus pallidus, and deep folia of the cerebellar cortex—the sites of predilection in anoxic encephalopathy. Microscopically, a widespread hyperplasia of protoplasmic astrocytes is visible in the deep layers of the cerebral cortex and in the cerebellar cortex as well as in thalamic and lenticular nuclei and other nuclear structures of the brainstem. In the necrotic zones, the medullated fibers and nerve cells are destroyed, with marginal fibrous gliosis; at the corticomedullary junction, in the striatum (particularly in the superior pole of the putamen), and in the cerebellar white matter, polymicrocavitation may be prominent. Protoplasmic astrocytic nuclei contain PAS-positive glycogen granules. Some nerve cells appear swollen and chromatolyzed, taking the form, we believe, of the so-called Opalski cells usually associated with Wilson disease. The similarity of the neuropathologic lesions in the familial and acquired forms of hepatocerebral disease is striking.

Pathogenesis It is evident that a close relationship exists between the acute, transient form of hepatic encephalopathy (hepatic coma) and the chronic, largely irreversible hepatocerebral syndrome; frequently one blends imperceptibly into the other. This relationship is reflected in the pathologic findings as well; the astrocytic hyperplasia and PAS-positive inclusions are identical in both forms of the disease, and the distribution of the destructive lesions follows closely the distribution of the astrocytic change. Also, both disorders are characterized by hyperammonemia, episodic in one and persistent in the other. Reducing the serum ammonia by the measures that are effective in acute hepatic encephalopathy will cause a recession of many of the chronic neurologic abnormalities, not completely but to an extent that permits the patient to function better.

It appears that the parenchymal damage in the chronic disease simply represents the most severe degree of a pathologic process that in its mildest form is reflected in an astrocytic hyperplasia alone.

Kernicterus

Kernicterus, formerly a common cause of congenital choreoathetosis, has now been virtually eliminated. It is discussed on page 1085.

Hypoparathyroidism

This condition and pseudohypoparathyroidism (page 1032) were mentioned in relation to the hereditary metabolic disorders. In the past, the usual cause of hypoparathyroidism was surgical removal of the parathyroid glands during subtotal thyroidectomy, although there were always idiopathic cases as well. With the more widespread use of radiation and drug therapy for thyroid disease, the number of surgically created cases has become small in proportion to nonsurgical ones. The latter may occur in pure form, presumably as an agene-sis of the parathyroid glands with unmeasurable levels of parathyroid hormone in the blood, or as part of the DiGeorge syndrome of agenesis of the thymus and parathyroid glands, organs that are embryologically derived from the third and fourth branchial clefts. Hypoparathyroidism is also part of a familial disorder in which a deficiency of thyroid, ovarian, and adrenal function, pernicious anemia, and other defects are combined, based presumably on a derangement of autoimmune mechanisms. Other causes are intestinal malabsorption, pancreatic insufficiency, and vitamin D deficiency. In all instances the low levels of parathormone and normal responses to injected hormone permit the recognition of a primary defect of the parathyroid glands and distinguish it from all other conditions in which there is hypocalcemia and hyperphosphatemia.

The clinical manifestations, mainly attributable to the effects of hypocalcemia, are tetany, paresthesias, muscle cramps, laryngeal spasm, and convulsions. Children with this disease may be irritable and show personality changes. In adults with chronic hypocalcemia, calcium deposits occur in the basal ganglia, dentate nuclei, and cerebellar cortex. In such patients we have observed unilateral tremor, a restless choreoathetotic hand, bilateral rigidity, slowness of movement and flexed posture resembling Parkinson disease, and ataxia of the limbs and gait—in various combinations. Interestingly, the multiple skeletal and developmental abnormalities that characterize both pseudo- and pseudo-pseudohypoparathyroidism (short stature, round face, short neck, stocky body build, shortening of metacarpal and metatarsal bones and phalanges from premature epiphyseal closure) are rarely seen in pure hypoparathyroidism.

A similar deposition of ferrocalt in the walls of small blood vessels of the lenticular and dentate nuclei and to a lesser extent in other parts of the brain is a common finding and is similar to that observed in normal older individuals but more severe. It also occurs in animals. Occasionally it reaches a degree of severity that destroys striatal or dentate neurons. In such cases, films of the skull and particularly CT scans will reveal the deposits. Cases of this type have been reported for years (page 1032). The cause of the deposits is unknown. Apparently some protein in the capillary walls has an avidity for both calcium and iron.

METABOLIC DISEASES PRESENTING AS CEREBELLAR ATAXIA

Cerebellar Ataxia Associated with Myxedema

The association of myxedema and cerebellar ataxia has been mentioned sporadically in medical writings since the latter part of the nineteenth century. Interest in this problem was revived in more recent years by Jellinek and Kelly, who described 6 such cases. All of them showed an ataxia of gait; in addition, some degree of ataxia of the arms and dysarthria were present in 4 instances, and nystagmus in 2. Cremer and coworkers have reported a similar clinical experience, based on a study of 24 patients with either primary or secondary hypothyroidism.

There have been only a few reports of the pathologic changes, and these are far from satisfactory. The myxedematous patient described by Price and Netsky had also been a serious alcoholic, and the clinical signs (ataxia of gait and of the legs) and pathologic changes (loss of Purkinje cells and gliosis of the molecular layer, most pronounced in the vermis) cannot be distinguished from those due to alcoholism and malnutrition. Scattered throughout the nervous system of their case were unusual glycogen-containing bodies, similar but not identical to corpora amylacea. These structures, designated myxedema bodies by Price and Netsky, were also observed in the cerebellar white matter of a second case of myxedema; there were no other neuropathologic changes, however, and this patient had shown no ataxia during life. It is difficult to know whether these peculiar bodies have anything to do with myxedema. If they do, it should be possible to demonstrate them in more than two cases. We have not seen them in one carefully studied case of myxedema, nor have they been described by others. Thyroid medication corrects the defect in motor coordination, raising doubt as to whether it could be based on a visible structural lesion.

Other metabolic disorders, some heritable, in which ataxia may be a leading manifestation include Whipple disease ([Chap. 33](#)), GM₂ gangliosidosis, sprue (discussed below), and a large number of neonatal and infantile aminoacidopathies. The various causes of cerebellar ataxia, including these, are summarized in [Table 5-1](#) (page 97).

Effects of Hyperthermia on the Cerebellum

The damaging effects of *hyperthermia*, like those of anoxia, involve the brain diffusely. In the case of hyperthermia, however, the changes are disproportionately severe in the cerebellum. The acute manifestations of profound hyperthermia are coma and convulsions, frequently complicated by shock and renal failure. Patients who survive the initial stage of the illness frequently show signs of widespread cerebral affection, such as confusion and pseudobulbar and spastic paralysis. These abnormalities tend to resolve gradually, leaving the patient with a more or less pure disorder of cerebellar function.

The most extensive account of the pathologic effects of hyperthermia is that of Malamud and colleagues. These authors studied 125 fatal cases of heat stroke, but their observations are probably applicable to hyperthermia of other types. In patients who survived less than 24 h, the changes consisted mainly of a loss of some of the Purkinje cells and swelling, pyknosis, and disintegration of those that remained. In cases surviving beyond 24 h, there was almost complete degeneration of the Purkinje cells, with gliosis throughout the cerebellar cortex as well as degeneration of the dentate nuclei. The changes in the cerebellar cortex were equally pronounced in the hemispheres and vermis. The unanswered question is whether high temperature alone is an adequate cause or must be combined with hypoxia and ischemia. It is of interest that we have not seen this syndrome in patients with infective fevers, malignant hyperthermia, or the malignant neuroleptic syndrome—either the neuropathologic changes or the clinical cerebellar syndrome in survivors.

Cerebellar Syndromes Associated with Celiac-Sprue and Jejunoileal Bypass

A progressive cerebellar ataxia of gait and limbs, sometimes with polymyoclonus in association with a gluten-sensitive enteropathy, has been the subject of several reports. The underlying lesion is a villus atrophy of the intestinal mucosa, consistent with celiac disease of children and sprue in adults. The neurologic disorder may appear several years after onset of the enteropathy and, in addition to ataxia, usually includes signs of peripheral neuropathy and, in some cases, myelopathy and encephalopathy (dementia). According to Finelli et al, neurologic abnormalities occur in approximately 10 percent of cases of adult celiac-sprue. This subject has been reviewed by [Bhatia et al](#) and recently by [Hadjivassiliou et al](#). The latter authors emphasize the frequent occurrence of ataxia in patients with gluten sensitivity (indicated by circulating antibodies to gliadin) but without overt signs of bowel disease. There is also a strong association (in more than 90 percent of patients) with the HLA DQ8 class II genotype. The few cases that have come to autopsy have shown severe cerebellar atrophy, a finding that may also be disclosed by MRI. Hadjivassiliou et al observed lymphocytic infiltration and perivascular cuffing in the cerebellar cortex and peripheral nerves in one autopsied case but not in another, changes that they took to represent immunologic injury to these parts. The main differential diagnostic considerations are paraneoplastic cerebellar degeneration and Whipple disease.

Vitamin E deficiency may induce a similar syndrome with features of spinocerebellar dysfunction (see page 1224).

Jejunoileal bypass operations, in addition to causing a chronic arthropathy, neuropathy, and vasculitic skin lesions, may give rise to an episodic confusion and cerebellar ataxia associated with a lactic acidosis and abnormalities of pyruvate metabolism. Overfeeding and fasting are provocative factors ([Dahlquist et al](#)).

METABOLIC DISEASE PRESENTING AS PSYCHOSIS AND DEMENTIA

The point has been made that milder forms of diseases that cause episodic stupor and coma, if persistent, may present as states of protracted confusion, difficult to distinguish from the dementias. Chronic hepatic encephalopathy and the syndromes of chronic hypoglycemia, chronic hypercalcemia (in multiple myeloma, metastatic cancer, and sarcoidosis), and dialysis encephalopathy all fall within this category. Unlike the common types of dementia described in [Chap. 21](#), the acquired metabolic diseases are nearly always accompanied by drowsiness, inattentiveness, and reduced alertness; i.e., by a clouding of the sensorium and inaccurate perceptions and interpretations—attributes that usually allow an encephalopathic confusional state to be distinguished from a dementia. If the onset of the illness is abrupt rather than gradual and of brief duration and if therapy reverses the condition, restoring full mental clarity, the conclusion is justified that one is dealing with a confusional state; but at any one time in the active phase of the disease the clinical state may resemble dementia.

In general hospitals, an episodic confusional state lasting days and weeks in the course of a medical illness or following an operation should always raise the suspicion of one of the aforementioned metabolic states. Usually, however, all of them can be excluded, and one falls back on a rather unsatisfactory interpretation—that a combination of drugs, fever, toxemia, and unspecifiable metabolic disorders is responsible. The “septic encephalopathy” described earlier in the chapter falls into this category.

In the endocrine encephalopathies, which are described below, the clinical phenomena may be even more abstruse, although they often take the form of a unique psychosis. Confusional states may be combined with agitation, hallucinations, delusions, anxiety, and depression, and the time span of the illness may be in terms of weeks and months rather than days. Certain aspects of the endocrine psychoses are discussed further on page 1641.

Cushing Disease and Corticosteroid Psychoses

Derangements of mental function that followed administration of adrenocorticotrophic hormone (ACTH) and then of corticosteroids have become the prototypes of iatrogenic psychoses. The same disturbances of mental function may accompany Cushing disease (page 715).

Our experience with this neuropsychiatric condition was derived originally from observations of patients receiving ACTH and later from patients receiving prednisone for a variety of neurologic and medical diseases. With low doses there is usually no psychic effect other than a sense of well-being and decreased fatigability. At higher doses (60 to 100 mg/day of prednisone), approximately 10 to 15 percent of patients become overly active, emotionally labile, and unable to sleep. Unless the dose is promptly reduced, there follows a progressive shift in mood, usually toward euphoria and hypomania—but sometimes toward depression and then inattentiveness, distractibility, and mild confusion. The EEG becomes less well modulated and slower frequencies appear. A minority of patients experience frank hallucinations and delusions, giving the illness a truly psychotic stamp and raising the suspicion of schizophrenia or manic-depressive disease. In nearly all instances, however, this mixture of confusion and mood change, in association with disordered cognitive function, distinguishes the iatrogenic corticosteroid psychosis. Withdrawal of medication relieves the symptoms, but full recovery may take several days to a few weeks, at which time, as with all confusional states and deliria, the patient has only a fragmentary recollection of events that occurred during the illness.

The neurologic basis of this condition is poorly understood. Its attribution to premorbid personality traits or a disposition to psychiatric illness is plausible but lacks convincing documentation. Part of the difficulty is the lack of knowledge of the role of these endocrine agents in normal cerebral metabolism. We have only incomplete knowledge, for example, as to how they act to reduce the volume of the edematous cerebral tissue around a tumor or to shrink the brain. Critical studies of cellular or subcellular metabolism and morphologic changes are lacking. “Cerebral atrophy” (ventricular enlargement and sulcal widening) has been shown radiologically in patients with Cushing disease and after a prolonged period of corticosteroid therapy, but the basis of this change also is unexplained ([Momose et al](#)). In most cases, withdrawal of steroids has led to reversal of symptoms and reduction in ventricular size, documented by repeated CT scans.

In patients with Cushing disease due to adrenal or basophilic pituitary tumors, mental changes suggestive of dementia and enlarged ventricles are not unusual. Here again there is a peculiar combination of mood changes and impaired cognitive function. A frank psychosis may occur. This condition is described more completely in [Chap. 57](#) and the attending polymyopathy, in [Chap. 51](#).

Thyroid Encephalopathies

Hyperthyroidism The neurology of thyrotoxicosis has proved to be particularly elusive. Allusions to psychosis are frequent in the medical literature, and some thyrotoxic patients have been observed with mental confusion, seizures, manic or depressive attacks, and delusions. Tremor is almost universal, and chorea occurs occasionally in various combinations with muscular weakness and atrophy, periodic paralysis, and myasthenia. In descriptions of the chorea, it is often not clear whether it was chorea, tremor, myoclonus, or just fidgetiness that was observed. Treatment of the hyperthyroidism gradually restores the mental state to normal, leaving one with no explanation of what had happened to the CNS.

Thyroid crisis or “storm” refers to a fulminant increase in the symptoms and signs of thyrotoxicosis—extreme restlessness, tachycardia, fever, vomiting, and diarrhea—leading to delirium or coma. In the past, this was a not uncommon postoperative event in patients poorly prepared for thyroid surgery. Now it is seen mainly in patients with inadequately treated or untreated thyrotoxicosis complicated by serious medical or surgical illness.

Hashimoto Encephalopathy Shaw and colleagues have described an encephalopathy consisting of confusion, altered consciousness, and prominent myoclonus, sometimes relapsing, in patients with Hashimoto disease (“Hashimoto encephalopathy”). Curiously, most have had normal thyroid function. There are, however, high titers of several antithyroid antibodies, including antibodies against thyroid peroxidase and thyroglobulin. Seizures—including myoclonic and rarely nonconvulsive status epilepticus—hemiparesis, ataxia, psychosis, and unusual tremors have been reported in individual cases. Often there are others in the family with autoimmune diseases. It has been the myoclonic aspect of the encephalopathy, a feature of all of our cases, that has led to consideration of this diagnosis. We have encountered several such cases, two of which were initially mistaken for Creutzfeldt-Jacob disease (subacute spongiform encephalopathy). Early descriptions included a pleocytosis and white matter lesions, but we have not noted these abnormalities. The encephalopathic symptoms and high titers of antithyroid antibodies responded well to steroid therapy. In the case of Newcomer and associates, a rapid reversal of thyrotoxic coma (and corticospinal signs) was effected by plasma exchange, in parallel with a reduction in T4 and T3 levels. The specific circulating antibodies and the response to corticosteroids and plasma exchange implicate an immune pathogenesis, similar to paraneoplastic “limbic encephalitis” and perhaps to lupus, as well as to the rare encephalopathy that occurs in patients with thymoma.

Hypothyroidism As a rule, the myxedematous patient is slow to react and psychomotor activity is reduced; but only in exceptional cases have we noted a significant change in cerebral function. When such a change has been observed, we have been more impressed with drowsiness, inattentiveness, and apathy. In two personally observed cases, the somnolence was so extreme that the patients could not stay awake long enough to be fed or examined. They were in a state of hypothermic stupor but exhibited no other neurologic abnormality. The extreme somnolence can be reversed within a few days by thyroid medication.

Hypothyroidism is associated with a number of distinctive myopathic disturbances, which are discussed in [Chap. 51](#). The ataxia and peripheral neuropathy that are sometimes observed in patients with myxedema are described in this chapter (above) and in [Chap. 46](#), respectively.

Cretinism and Neonatal Myxedema This form of severe hypothyroidism, occurring during intrauterine life (hypothyroidism in mother and fetus) or postnatally as a hereditary or acquired thyroid disease, is probably the most frequent and potentially preventable and correctable metabolic mental defect in the world. A perspective on its relative frequency among neonatal metabolic disorders is given in [Table 37-1](#). Although the condition is most common in goitrous regions where there is a lack of iodine, it may also be due to any of several genetically determined defects in thyroxin synthesis that have come to light in recent years ([Vassart et al](#)). In areas of endemic cretinism, additional factors may be operative, such as the widespread ingestion of cassava, which contains a toxic goitrogen that inhibits the uptake of iodine by the thyroid.

As a rule, the symptoms and signs of congenital thyroid deficiency are not recognizable at birth but become apparent only after a few weeks; more often the diagnosis is first made between the sixth and twelfth months of life. Physiologic jaundice tends to be severe and prolonged (up to 3 months), and this, along with widening of the posterior fontanelle and mottling of the skin, should raise suspicion of the disease.

In general, two types of early life hypothyroidism are recognized—sporadic and endemic. The sporadic type occurs occasionally in developed countries (less than once in 4000 births) and is consequent upon a congenital metabolic or anatomic disorder of the thyroid gland. At birth, the gland is either absent or represented by cysts, indicating a failure of development or a destructive lesion. In the sporadic form, in the latter part of the first year, stunting of growth and delay in psychomotor development become evident. Untreated, the child is severely retarded but placid and good-natured; such children sleep contentedly for longer periods than normal children. Sitting, standing, and walking are delayed. Movements are slow, and if tendon reflexes can be obtained, their relaxation time is clearly delayed. The body temperature is low, and the extremities are cold and cyanotic. Although the head is small, the fontanelles may not close until the sixth or seventh year, and there is delayed ossification. This type of hypothyroidism is preventable by treatment with thyroid hormone.

Endemic cretinism is most common in developing countries, with an estimated incidence in these areas of 5 to 15 percent. DeLong and colleagues, on the basis of epidemiologic surveys in Ecuador, Zaire, and western China, have distinguished two forms of endemic cretinism—neurologic and myxedematous. The occurrence of the two different types is governed by the timing, duration, and severity of the iodine deficiency ([Thilly et al](#)).

The *neurologic form of endemic cretinism* is characterized by varying degrees of deaf-mutism or lesser degrees of hearing loss, dysarthria, proximal limb and truncal

rigid-spastic motor disorder involving mainly the lower extremities, and mental deficiency of a characteristic type. In the most severely affected, there is also strabismus, kyphoscoliosis, underdevelopment of leg muscles, and frontal lobe release signs. Bone age, head size, and height are normal and there are none of the coarse facial features of the myxedematous form. In the so-called *myxedematous form of endemic cretinism*, short stature, microcephaly, coarse facial features, and retarded psychomotor development are the main features. There is no deafness or spastic rigidity of the limbs. In typical instances, the face is pale and puffy; the skin dry; the hair coarse, scanty, and dry; the eyelids thickened; the heavy lips parted by the enlarged tongue; the forehead low; and the base of the nose broad. There are fat pads above the clavicles and in the axillae. The abdomen is protuberant, often with an umbilical hernia, and the head is small—a physical appearance that prompted William Boyd to remark: “What was intended to be created in the image of God has turned out to be the pariah of nature, all for the want of a little thyroid.”

DeLong and others attribute neurologic cretinism to a lack of available iodine in the mother and fetus during the second and third trimesters of pregnancy; neither mother nor fetus elaborate thyroxin. The first and part of the second trimester developmental period, which does not require iodine or thyroxin, passes normally and the general morphology of the brain is normal. It is during the second trimester, when the cochleas and the neuronal population of the cerebral cortex and basal ganglia are forming, that these structures suffer irreparable damage. The effects of this midfetal hypothyroidism and iodine deficiency cannot be corrected by giving thyroid hormone at birth and thereafter. It can be prevented only by providing iodine therapy to the mother before and during the first trimester of pregnancy ([Cao et al](#)). The myxedematous form of cretinism is more likely to occur from lack of thyroid hormone in the late second and the third trimesters.

The mental defect ranges from apathy and absence of social interaction to an alert, cooperative state, but a backwardness in higher-order thinking and verbal facility is always evident. Retentive memory and apperception are commensurate with overall intellectual competence as judged by the level of mental associations and capacity for abstract thought. The status of the thyroid gland varies; among neurologic cretins, about half are goitrous or have palpable glands; in the rest, the glands are atrophied; practically all the myxedematous cretins are athyreotic. Although typical examples of neurologic and myxedematous hypothyroidism are readily distinguished, both types may exist in the same endemic area and the stigmata of both forms may be recognized in the same individual. The QRS complex of the electrocardiogram is of low voltage; the EEG is slower than normal, with less alpha activity; the CSF contains an excess of protein (50 to 150 mg/dL); and the serum T3 and T4, protein-bound iodine, and radioactive iodine uptake are all subnormal. Serum cholesterol is increased (300 to 600 mg/dL).

At autopsy the brain of neurologic cretinism, though small, is normally formed, with all central and brainstem structures and cortical sulcation intact. A reduction in number of nerve cells was described by Marinesco, especially in the fifth cortical layer, but others have not confirmed this finding. The use of Golgi and other silver techniques has shown decreased interneuronal distances (packing density is increased, as in the immature cortex) and a deficiency of neuropil. The latter change is due to a poverty of dendritic branchings and crossings, and presumably there is a decrease of the synaptic surfaces of cells ([Eayrs](#)). Thyroid hormone appears to be essential, not for neuronal formation and migration but for dendritic-axonic development and organization.

There is fairly substantial evidence that the administration of iodinated oil to hypothyroid women before and during the first trimester of pregnancy prevents sporadic and endemic cretinism. Treatment begun during the second trimester protects the fetal brain to a varying degree. Treatment that is started after the beginning of the third trimester does not improve the neurologic status, although head growth and statural development may improve slightly ([Cao et al](#)). In sporadic cretinism, if the condition is recognized early, say at birth, and treated consistently with potent thyroid hormones, statural and mental development can be stimulated to normal or near-normal levels. Extent of recovery depends on the severity and duration of intrauterine hypothyroidism, i.e., its duration before treatment was begun and the adequacy of therapy. In most patients, some degree of mental deficiency persists throughout life.

Pancreatic Encephalopathy

This term was introduced by Rothermich and von Haam in 1941 to describe what they considered to be a fairly uniform clinical state in patients with acute abdominal symptoms referable to pancreatic disease, mainly pancreatitis. The encephalopathy, as they described it, consists of an agitated, confused state, sometimes with hallucinations and clouding of consciousness, dysarthria, and changing rigidity of the limbs—all of which fluctuate over a period of hours or days. Coma and quadriplegia have been reported. At autopsy, a variety of lesions have been described; two cases have had central pontine myelinolysis and others have had small foci of necrosis and edema, petechial hemorrhages, and “demyelination” scattered through the cerebrum, brainstem, and cerebellum. These have been uncritically attributed to the action of released lipases and proteases from the action of pancreatic enzymes (see review of this subject by [Sharf and Levy](#)). The term *pancreatic encephalopathy* has also been applied to a depressive illness which seems to occur with disproportionate frequency before the symptoms of a pancreatic tumor become apparent.

The status of this entity, in the authors' opinion, is uncertain. Pallis and Lewis also express reservations and suggest that before such a diagnosis can be seriously entertained in a patient with acute pancreatitis, one must exclude delirium tremens, shock, renal failure, hypoglycemia, diabetic acidosis, hyperosmolality, and hypocalcemia or hypercalcemia—any one of which may complicate the underlying disease. Other cases conform to the encephalopathy of multiorgan failure discussed earlier. Several patients in our care who were thought originally to have pancreatic encephalopathy proved to have sequential strokes from marantic endocarditis.

[Nutritional Deficiencies Secondary to Diseases of the Gastrointestinal Tract](#)

[Inherited Vitamin-Responsive Neurologic Diseases](#)

[Chapter References](#)

Among nutritional disorders, those of the nervous system occupy a position of special interest and importance. The early studies of beriberi, at the turn of the century, were largely responsible for the discovery of thiamine, and consequently for the modern concept of deficiency disease. Despite the notable achievements in the science of nutrition that followed the discovery of vitamins, diseases due to nutritional deficiency—and particularly those of the nervous system—continue to represent a worldwide health problem of serious proportions. In Far Eastern communities, where the diet consists mainly of highly milled rice, there is still a significant incidence of beriberi. In other underdeveloped countries, deficiency diseases are endemic, the result of chronic dietary deprivation. And the ultimate effects on the nervous system of mass starvation, involving entire nations of the African continent, is alarming to contemplate.

It comes as a surprise to many physicians that deficiency diseases are also common in the United States and other parts of the western world. To a large extent this is attributable to the prevalence of alcoholism. Relatively less common causes are dietary faddism and impaired absorption of dietary nutrients (which occurs in patients with celiac sprue, pernicious anemia, or surgical exclusion of portions of the gastrointestinal tract—for treatment of obesity or other reasons). Finally, there are the deficiencies induced by the use of vitamin antagonists or certain drugs, such as isonicotinic acid hydrazide (INH), which is used in the treatment of tuberculosis and interferes with the enzymatic function of pyridoxine.

General Considerations

The term *deficiency* is used throughout this chapter in its strictest sense, to designate disorders that result from *the lack of an essential nutrient(s) in the diet or from a conditioning factor that increases the need for these nutrients*. The most important of these nutrients are the vitamins, more specifically, members of the B group—thiamine, nicotinic acid, pyridoxine, pantothenic acid, riboflavin, folic acid, and cobalamin (vitamin B₁₂). Most deficiency diseases cannot be related to the lack of a single vitamin (subacute combined degeneration of the cord, due to vitamin B₁₂ deficiency, is a notable exception). Usually the effects of several vitamin deficiencies can be recognized. This statement should not obscure the fact that particular manifestations of deficiency disease (e.g., the ocular palsies of Wernicke disease) are indeed related to a deficiency of a specific nutrient, nor should it diminish the need to identify such relationships.

Nutritional diseases of the nervous system are not simply a matter of vitamin deprivation, however. Practically always, the general signs of undernutrition, such as circulatory abnormalities and loss of subcutaneous fat and muscle bulk, are associated. Furthermore, a total lack of vitamins, as in starvation, is rarely associated with the classic deficiency syndromes of beriberi or pellagra; a certain amount of food is necessary to produce them. An excessive intake of carbohydrate relative to the supply of thiamine favors the development of a thiamine deficiency state. All deficiency diseases, including those of the nervous system, are influenced by factors such as exercise, growth, pregnancy, and infection, which increase the need for essential nutrients, and by disorders of the liver and the gastrointestinal tract, which may interfere with the synthesis and absorption of these nutrients.

As already mentioned, alcoholism is an important factor in the causation of nutritional diseases of the nervous system. Alcohol acts mainly by displacing food in the diet but also by adding carbohydrate calories (alcohol is burned almost entirely as carbohydrate), thus increasing the need for thiamine. There is some evidence as well that alcohol impairs the absorption of thiamine and other vitamins from the gastrointestinal tract.

In infants and young children, a reduction of protein and caloric intake (so-called protein-calorie malnutrition, or PCM) has a devastating effect upon body growth. Whether or not PCM also hinders the growth of the brain, with consequent effects upon intellectual and behavioral development, cannot be answered as readily. The data bearing on this matter are discussed in the last part of the chapter.

Deficiency diseases of the nervous system may occur in pure form and are so described in the following pages. But more often, the symptoms of other deficiencies are added, i.e., the deficiency diseases occur in various combinations. Characteristic also of the nutritional diseases is the involvement of both the central and peripheral nervous systems, an attribute shared only with certain hereditary metabolic disorders.

The following deficiency diseases are discussed in this chapter:

1. Wernicke disease and Korsakoff psychosis
 2. Nutritional polyneuropathy (neuropathic beriberi)
 3. Deficiency amblyopia (nutritional optic neuropathy; “tobacco-alcohol” amblyopia)
 4. Pellagra (with some remarks on spinal spastic ataxia and nicotinic acid deficiency encephalopathy)
 5. The syndrome of amblyopia, painful neuropathy, and orogenital dermatitis (so-called Strachan syndrome)
 6. Subacute combined degeneration of the spinal cord (vitamin B₁₂ deficiency)
 7. Neurologic disorders due to a deficiency of pyridoxine and possibly other B vitamins (pantothenic acid, riboflavin, folic acid)
 8. Vitamin E deficiency

In addition, attention is drawn to several distinctive neurologic disorders in which nutritional deficiency may play a role, although this has not been proved: (1) “alcoholic” cerebellar degeneration, (2) central pontine and extrapontine myelinolysis, and (3) primary degeneration of the corpus callosum (Marchiafava-Bignami disease). Also, some comments are made about PCM, the neurologic disorders consequent upon intestinal malabsorption, and the rare, hereditary vitamin-responsive diseases. Deficiencies of trace elements, because of their rarity, are not discussed; only iodine deficiency (cretinism) is of much importance in humans, and it is discussed in the chapter on acquired metabolic disease. Deficiencies of other elements have been reviewed by Fowden and colleagues.

The Wernicke-Korsakoff Syndrome

Wernicke disease and the Korsakoff amnesic state are common neurologic disorders that have been recognized since the 1880s. *Wernicke disease* (originally called polioencephalitis hemorrhagica superioris) is characterized by nystagmus, abducens and conjugate gaze palsies, ataxia of gait, and mental confusion. These symptoms develop acutely or subacutely and may occur singly or, more often, in various combinations. Wernicke disease is due to nutritional deficiency, more specifically to a deficiency of thiamine, and is observed mainly, though far from exclusively, in alcoholics.

The *Korsakoff amnesic state* (Korsakoff psychosis) refers to a unique mental disorder in which retentive memory is impaired out of proportion to other cognitive functions in an otherwise alert and responsive patient. This amnesic disorder, like Wernicke disease, is most often associated with alcoholism and malnutrition, but it

may be a symptom of various other diseases that have their basis in lesions of the medial thalami or the inferomedial portions of the temporal lobes, such as infarction in the territory of the temporal lobe branches of the posterior cerebral arteries, hippocampal damage after cardiac arrest, third ventricular tumors, or herpes simplex encephalitis. A Korsakoff type of memory disturbance may also follow lesions that involve the basal septal nuclei of the frontal lobe. Transient impairments of retentive memory of the Korsakoff type may be the salient manifestations of temporal lobe epilepsy, concussive head injury, and a unique disorder known as transient global amnesia; and a permanent abnormality of this sort may be the most prominent feature of anoxic encephalopathy and of Alzheimer disease. The anatomic basis of the Korsakoff syndrome is discussed further in [Chap. 21](#).

In the alcoholic, nutritionally deficient patient, the Korsakoff amnesic state is usually associated with Wernicke disease. Stated another way, *Korsakoff psychosis* is the psychic manifestation of Wernicke disease. For this reason and others elaborated below, the term *Wernicke disease* or *Wernicke encephalopathy* should be applied to a symptom complex of ophthalmoparesis, nystagmus, ataxia, and an acute apathetic-confusional state. If an enduring defect in learning and memory is added, the symptom complex is appropriately designated as the *Wernicke-Korsakoff syndrome*.

Historical Note In 1881, Carl Wernicke first described an illness of sudden onset characterized by paralysis of eye movements, ataxia of gait, and mental confusion. Swelling of the optic discs and retinal hemorrhages were also said to be present. His observations were made in 3 patients, of whom 2 were alcoholics and 1 was a young woman with persistent vomiting following the ingestion of sulfuric acid. In each of these patients there was progressive stupor and coma, culminating in death. The pathologic changes described by Wernicke consisted of punctate hemorrhages, primarily affecting the gray matter around the third and fourth ventricles and aqueduct of Sylvius; he considered these changes to be inflammatory in nature and confined to the gray matter, hence his designation “polioencephalitis hemorrhagica superioris.” In the belief that Gâyet had described an identical disorder in 1875, the term Gâyet-Wernicke is used frequently by French authors. Such a designation is hardly justified insofar as the clinical signs and pathologic change in Gâyet’s patient differed from those of Wernicke’s patients in all essential details.

In a similar vein, a number of early writers, beginning with Magnus Huss in 1852, made casual reference to a disturbance of memory in the course of chronic alcoholism. However, the first comprehensive account of this disorder was given by the Russian psychiatrist S. S. Korsakoff in a series of articles published between 1887 and 1891 (for English translation and commentary, see reference by [Victor and Yakovlev](#)). Korsakoff stressed the relationship between “neuritis” (a term used at that time for all types of peripheral nerve disease) and the characteristic disorder of memory, which he believed to be “two facets of the same disease” and which he called “psychosis polyneuritica.” But he also made the points, generally disregarded by subsequent authors, that neuritis need not accompany the characteristic amnesic syndrome and that both disorders could affect nonalcoholic as well as alcoholic patients. His clinical descriptions were remarkably complete and have hardly been surpassed to the present day.

It is of interest that the relationship between Wernicke disease and Korsakoff polyneuritic psychosis was appreciated neither by Wernicke nor by Korsakoff. Murawieff, in 1897, first postulated that a single cause was responsible for both. The intimate clinical relationship was established by Bonhoeffer in 1904, who stated that in all cases of Wernicke disease he found neuritis and an amnesic psychosis. Confirmation of this relationship on pathologic grounds came much later (for further details, see the monograph by [Victor et al](#)).

Clinical Features The incidence of the Wernicke-Korsakoff syndrome cannot be stated with precision, but it is has, until relatively recent years, been a common disorder, judging from our experience. At the Cleveland Metropolitan General Hospital, for example, in a consecutive series of 3548 autopsies in adults (for the period 1963 to 1976), the pathognomonic lesions were found in 77 cases (2.2 percent). The disease affects males only slightly more frequently than females, and the age of onset is fairly evenly distributed between 30 and 70 years. In the past two decades, the incidence of the Wernicke-Korsakoff syndrome has fallen significantly in the alcoholic population. However, it is being recognized with increasing frequency among nonalcoholic patients in a variety of clinical settings, mainly iatrogenic ones.

The triad of clinical features described by Wernicke—ophthalmoplegia, ataxia, and disturbances of mentation and consciousness—is still diagnostically useful provided that the diagnosis is suspected and the signs are carefully sought. Often the disease begins with ataxia, followed in a few days or weeks by mental confusion; or there may be the more or less simultaneous onset of ataxia, nystagmus, and ophthalmoparesis, with or without confusion. Less often, one component of this triad may be the sole manifestation of the disease. A description of each of the major manifestations follows.

Ocularmotor Abnormalities The diagnosis of Wernicke disease is made most readily on the basis of the ocular signs. These consist of (1) nystagmus that is both horizontal and vertical, (2) weakness or paralysis of the lateral rectus muscles, and (3) weakness or paralysis of conjugate gaze. Usually there is some combination of these abnormalities (see [Chap. 14](#)).

Next to nystagmus, the most frequent ocular abnormality is lateral rectus weakness, which is bilateral but not necessarily symmetrical and is accompanied by diplopia and internal strabismus. With complete paralysis of the lateral rectus muscles, nystagmus is initially absent in the abducting eyes, but it becomes evident as the weakness improves. The palsy of conjugate gaze varies from merely a nystagmus on extreme gaze to a complete loss of ocular movement in that direction. This applies to both horizontal and vertical movements, abnormalities of the former being somewhat more frequent. Paralysis of downward gaze is an unusual manifestation, but internuclear ophthalmoplegia is common. In advanced stages of the disease there may be a complete loss of ocular movements, and the pupils, which are usually spared, may become miotic and nonreacting. Ptosis, small retinal hemorrhages, involvement of the near-far focusing mechanism, and evidence of optic neuropathy occur occasionally, but we have never observed papilledema in this disease. Although the aforementioned ocular signs are highly characteristic of Wernicke disease, disappearance of nystagmus and an improvement in ophthalmoparesis within hours or a day or two of the administration of thiamine will confirm the diagnosis.

Ataxia Essentially the ataxia is one of stance and gait, and in the acute stage of the disease it may be so severe that the patient cannot stand or walk without support. Lesser degrees are characterized by a wide-based stance and a slow, uncertain, short-stepped gait; the mildest degrees are apparent only in tandem walking. In contrast to the gross disorder of locomotion is the relative infrequency of a limb ataxia and intention tremor; when present, they are more likely to be elicited by heel-to-knee than by finger-to-nose testing. Scanning speech is present only rarely.

Disturbances of Consciousness and Mentation These are present in some form in all but 10 percent of patients. Four types of deranged mentation and consciousness can be recognized. By far the commonest disturbance is a *global confusional state*. The patient is apathetic, inattentive, and indifferent to his surroundings. Spontaneous speech is minimal and many questions are left unanswered, or the patient may suspend conversation and drift off to sleep, although he can be aroused without difficulty. Such questions as are answered by the patient betray disorientation in time and place, misidentification of those around him, and an inability to grasp the immediate situation. Many of the patient’s remarks are irrational and lack consistency from one moment to another. If the patient’s interest and attention can be maintained long enough to ensure adequate testing, one finds that memory and learning ability are also impaired. In response to the administration of thiamine or an adequate diet, the patient rapidly becomes more alert and attentive and more capable of taking part in mental testing. Then the most prominent abnormality is one of retentive memory (Korsakoff amnesic state).

About 15 percent of patients show the signs of alcohol withdrawal, i.e., hallucinations and other disorders of perception, confusion, agitation, tremor, and overactivity of autonomic nervous system function. These symptoms are evanescent in nature and usually mild in degree.

Although drowsiness is a common feature of the global confusional state, stupor and coma are rare as *initial* manifestations of Wernicke disease. However, if the early signs of the disease are not recognized and the patient remains untreated, there occurs a progressive depression of the state of consciousness, with stupor, coma, and death in a matter of a week or two, just as occurred in Wernicke’s original cases. Autopsy series of Wernicke disease are heavily weighted with cases of the latter type, often undiagnosed during life ([Harper](#); [Torvik et al](#)).

Some patients are alert and responsive from the time they are first seen and already show the characteristic features of the Korsakoff amnesic state. In a small number of such patients, the amnesic state is the only manifestation of the syndrome, and no ocular or ataxic signs (other than possibly nystagmus) can be discerned. The memory disorder, which constitutes the chronic and truly crippling feature of the Wernicke-Korsakoff syndrome, is described below.

The Amnesic State As indicated in [Chap. 21](#), the core of the amnesic disorder is a defect in learning (*anterograde amnesia*) and a loss of past memories (*retrograde amnesia*). The defect in learning (memorization) can be remarkably severe. The patient may be incapable, for example, of committing to memory three simple facts (such as the examiner’s name, the date, and the time of day), despite countless attempts; the patient can repeat each fact as it is presented, indicating that he understands what is wanted of him and that “registration” is intact, but by the time the third fact is repeated, the first may have been forgotten. However, certain subtle learning may take place; for example, with repeated trials, the patient may learn mirror writing or to negotiate a maze, despite no recollection of ever having learned these tasks.

Anterograde amnesia is always coupled with a disturbance of past or remote memory (retrograde amnesia). The latter disorder is usually severe in degree, though rarely complete, and covers a period that antedates the onset of the illness by several years. Characteristically, a few isolated events and information from the past are retained, but these are related without regard for the intervals that separated them or for their proper temporal sequence. Usually the patient “telescopes” events, sometimes the opposite. This aspect of the memory disorder becomes prominent as the initial (global confusional) stage of the illness subsides and some improvement in memory function occurs; this may account for certain instances of confabulation (see below).

It is probably true that memories of the recent past are more severely impaired than those of the remote past (Ribot's rule); language, computation, knowledge acquired in school, and all habitual actions are preserved. This is not to say that all remote memories are intact. These are not as readily tested as more recent memories, and the two are therefore difficult to compare. It is our impression that there are gaps and inaccuracies in memories of the distant past in practically all cases of the Korsakoff amnesic state and serious impairments in many of them.

It should be emphasized that the cognitive impairment of the Korsakoff patient cannot be explained in terms of memory loss alone, even though this is the most critical functional loss. Psychologic testing discloses that certain cognitive and perceptual functions that depend little or not at all on retentive memory are also impaired. The most consistent failure is with the digit symbol task and, to a lesser degree, with arithmetic and block design. Also, as a rule, the Korsakoff patient has no insight into his illness and is characteristically apathetic and inert, lacking in spontaneity and initiative and indifferent to everything and everybody around him. However, the patient has a relatively normal capacity to reason with data immediately before him.

Confabulation is generally considered to be a specific feature of Korsakoff psychosis. The validity of this view depends largely on how one defines confabulation, and there is no uniformity of opinion on this point. Our observations do not support the oft-repeated statement that the Korsakoff patient fills the gaps in his memory with confabulation. In the sense that gaps in memory exist and that whatever the patient supplies in place of the correct answers fills these gaps, the statement is incontrovertible. It is hardly explanatory, however. The implication that confabulation is a deliberate attempt to hide the memory defect, out of embarrassment or for other reasons, is probably not correct. In fact, the opposite seems to pertain: as the patient improves and become more aware of a defect in memory, the tendency to confabulate becomes less.

In our experience, confabulation is associated with two phases of the Wernicke-Korsakoff syndrome: the initial phase, in which profound general confusion dominates the disease; and the convalescent phase, in which the patient recalls fragments of past experience in a distorted fashion. Events that were separated by long intervals are juxtaposed or related out of sequence, so that the narrative has an implausible or fictional aspect. Whether one designates the latter defect as confabulation or as a particular defect of retentive memory is academic. In the chronic, stable state of the disease, confabulation is usually absent. These and other aspects of confabulation are discussed more fully in the monograph by Victor and colleagues.

Other Clinical Abnormalities Signs of *peripheral neuropathy* are found in more than 80 percent of patients with the Wernicke-Korsakoff syndrome. In most of them the neuropathic disease is mild and does not account for the disorder of gait, but it may be so severe that stance and gait cannot be tested. In a small number, retrobulbar neuropathy is added. Despite the frequency of peripheral neuropathy, overt signs of beriberi heart disease are rare. However, indications of disordered cardiovascular function such as tachycardia, exertional dyspnea, postural hypotension, and minor electrocardiographic abnormalities are frequent; occasionally, the patient dies suddenly, following only slight exertion. These patients may show an elevation of cardiac output associated with low peripheral vascular resistance—abnormalities that revert to normal after the administration of thiamine. *Postural hypotension* and syncope are common findings in Wernicke disease and are probably due to impaired function of the autonomic nervous system, more specifically to a defect in the sympathetic outflow ([Birchfield](#)). There may be mild *hypothermia*. Patients with the Korsakoff amnesic state may have a demonstrably *impaired olfactory discrimination*. This deficit, like the notable apathy that is present in most Wernicke patients, is probably attributable to a lesion of the mediodorsal nucleus of the thalamus and its connections and not to a lesion of the peripheral olfactory system ([Mair et al](#)).

Ancillary Laboratory Findings Vestibular function, as measured by the response to standard ice-water caloric tests, is universally impaired in the acute stage of Wernicke disease ([Ghez](#)). Vertigo is not a complaint, however. To this abnormality of function, which is bilateral and more or less symmetrical, the term *vestibular paresis* has been applied. It probably accounts for the severe disequilibrium in the initial stage of the illness. The CSF in uncomplicated cases of the Wernicke-Korsakoff syndrome is normal or shows only a modest elevation of the protein content. Protein values above 100 mg/dL or a pleocytosis should suggest the presence of a complicating illness—subdural hematoma and meningeal infection being the most common.

Blood pyruvate is elevated in untreated cases of Wernicke disease, but *blood transketolase* activity is a more accurate index of the thiamine deficiency. Transketolase, one of the enzymes of the hexose monophosphate shunt, requires thiamine pyrophosphate (TPP) as a cofactor. In normal adult subjects, transketolase values (expressed as sedoheptulose-7-phosphate produced per milliliter per hour) range from 90 to 140 mg and the TPP effect from 0 to 10 percent, depending upon the degree of vitamin supplementation. Before specific treatment with thiamine, patients with Wernicke disease show a marked reduction in their transketolase activity (as low as one-third of normal values) and a striking TPP effect (up to 50 percent). Restoration of these values toward normal occurs within a few hours of the administration of thiamine, and completely normal values are usually attained within 24 h.

An important abnormality of transketolase has been described by Blass and Gibson. They found that transketolase in cultured fibroblasts from four alcoholics with Wernicke-Korsakoff disease bound TPP less avidly than did the transketolase from control lines. Presumably this defect in transketolase would be insignificant if the diet were adequate but would be deleterious if the diet were low in thiamine. These findings, which have been corroborated by Mukherjee and colleagues, suggest a hereditary factor in the genesis of Wernicke-Korsakoff disease and possibly may explain why only a small proportion of nutritionally deficient alcoholics develop this disease.

Only about half the patients with Wernicke-Korsakoff disease show electroencephalographic (EEG) abnormalities, consisting of diffuse mild to moderate slow activity. Total cerebral blood flow and cerebral oxygen and glucose consumption may be greatly reduced in the acute stages of the disease, and these defects may still be present after several weeks of treatment ([Shimojyo et al](#)). These observations indicate that significant reductions in brain metabolism need not be reflected in EEG abnormalities or in depression of the state of consciousness and that the latter is more a function of the location of the lesion than of the overall degree of metabolic defect.

The acute lesions of the Wernicke-Korsakoff syndrome, both the medial thalamic and periaqueductal ones, can be demonstrated by magnetic resonance imaging ([Donnal et al](#), [Gallucci et al](#)). This procedure is particularly useful in patients in whom stupor or coma has supervened or in whom ocular and ataxic signs are otherwise inevident ([Victor, 1990](#)).

Course of the Illness The mortality rate in the acute phase of Wernicke disease was 17 percent in our series of patients. Mainly the fatalities were attributable to hepatic failure and to infection (pneumonia, pulmonary tuberculosis, and septicemia being the most common). Some deaths were undoubtedly due to the effects of thiamine deficiency that had reached an irreversible stage.

Most patients respond in a fairly predictable manner to the administration of thiamine, as detailed further on. The most dramatic improvement is in the ocular manifestations, as already mentioned. Recovery *begins* often within hours after the administration of thiamine and practically always within several days. This effect is so constant that a failure of the ocular palsies to respond to thiamine should raise doubts about the diagnosis of Wernicke disease. Sixth nerve palsies, ptosis, and vertical gaze palsies recover *completely* within a week or two in most cases, but vertical nystagmus may sometimes persist for several months. Horizontal gaze palsies recover completely as a rule, but in 60 percent of cases a fine horizontal nystagmus remains as a permanent sequela. In this respect, horizontal nystagmus is unique among the ocular signs.

In comparison with the ocular signs, improvement of ataxia is somewhat delayed. About 40 percent of patients recover completely from ataxia. The remainder recover incompletely or not at all and are left with a slow, shuffling, wide-based gait and inability to walk tandem. The residual gait disturbances and horizontal nystagmus provide a means of identifying obscure and chronic cases of dementia as alcoholic-nutritional in origin. Vestibular function improves at about the same rate as the ataxia of gait, and recovery is usually but not always complete.

The early symptoms of apathy, drowsiness, and global confusion invariably recede, and as they do so the defect in memory and learning stands out more clearly. The memory disorder, once established, recovers completely or almost completely in only 20 percent of patients. The remainder are left with varying degrees of permanent disability.

It is apparent from the foregoing account that Wernicke disease and Korsakoff psychosis are not separate diseases but that *the changing ocular and ataxic signs and the transformation of the global confusional state into an amnesic syndrome are simply successive stages in a single disease process*. Of 186 patients in our series who presented with Wernicke disease and survived the acute illness, 157 (84 percent) showed this sequence of clinical events. As a corollary, a survey of alcoholic patients with Korsakoff psychosis in a state mental hospital disclosed that in most the illness had begun with the symptoms of Wernicke disease, and that about 60 percent of them still showed the ocular and/or cerebellar stigmata of Wernicke disease many years after the onset.

Neuropathologic Findings and Clinical-Pathologic Correlation Patients who die in the acute stages of Wernicke disease show symmetrical lesions in the paraventricular regions of the thalamus and hypothalamus, mammillary bodies, periaqueductal region of the midbrain, floor of the fourth ventricle (particularly in the regions of the dorsal motor nuclei of the vagus and vestibular nuclei), and superior cerebellar vermis. Lesions are consistently found in the mammillary bodies and less consistently in other areas. The microscopic changes are characterized by varying degrees of necrosis of parenchymal structures. Within the area of necrosis, nerve cells are lost, but usually some remain; some of these are damaged, but others are intact. Myelinated fibers are more affected than neurons. These changes are accompanied by a prominence of the blood vessels, although in some cases there appears to be a primary endothelial proliferation. In the areas of parenchymal damage there is astrocytic and microglial proliferation. Discrete hemorrhages were found in only 20 percent of our cases, and many of them appeared to be agonal in nature. The cerebellar changes consist of a degeneration of all layers of the cortex, particularly of the Purkinje cells; usually this lesion is confined to the superior parts of the vermis, but in advanced cases the cortex of the most anterior parts of the anterior lobes is involved as well. Of interest is the fact that the lesions of Leigh's encephalomyelopathy, in which a disorder of pyruvate metabolism has been found (page 1042), bear a close resemblance to those of Wernicke disease in both their distribution and their histologic characteristics.

The ocular muscle and gaze palsies are attributable to lesions of the sixth and third nerve nuclei and adjacent tegmentum and the nystagmus to lesions in the regions of the vestibular nuclei. The latter are also responsible for the loss of caloric responses and probably for the gross disturbance of equilibrium that characterizes the initial stage of the disease. The lack of significant destruction of nerve cells in these lesions accounts for the rapid improvement and the high degree of recovery of oculomotor and vestibular functions. The persistent ataxia of stance and gait is due to the lesion of the superior vermis of the cerebellum; ataxia of individual movements of the legs is attributable to an extension of the lesion into the anterior parts of the anterior lobes. Hypothermia, which occurs sometimes as a presenting feature of Wernicke disease, is probably attributable to lesions in the posterior and posterolateral nuclei of the hypothalamus (experimentally placed lesions in these parts have been shown to cause hypothermia or poikilothermia in monkeys).

The topography of the neuropathologic changes in patients who die in the chronic stages of the disease, when the amnesic symptoms predominate, is much the same as the changes in the acute stages of Wernicke disease. Apart from the expected differences in age of the glial and vascular reactions, the only important difference has to do with the involvement or lack of involvement of the medial dorsal and anterior nuclei of the thalamus. The medial parts of these nuclei were consistently involved in our patients who had shown the Korsakoff amnesic state during life; they were not involved in patients who had had no persistent amnesic symptoms. The mammillary bodies were affected in all of the patients, both those with the amnesic defect and those without. These observations suggest that the lesions responsible for the memory disorder are those of the thalami, predominantly of the medial dorsal nuclei (and their connections with the medial temporal lobes and amygdaloid nuclei, i.e., a thalamic amnesic state), and not those of the mammillary bodies, as is frequently stated. It is also notable that the hippocampal formations, the site of damage in many other types of Korsakoff memory loss, are intact.

Treatment of the Wernicke-Korsakoff Syndrome Wernicke disease constitutes a medical emergency, and its recognition (or even the suspicion of its presence) demands the *immediate administration of thiamine*. The prompt use of thiamine prevents progression of the disease and reverses those lesions that have not yet progressed to the point of fixed structural change. In patients who show only ocular signs and ataxia, the administration of thiamine is crucial in preventing the development of an irreversible amnesic state.

Although 2 to 3 mg of thiamine may be sufficient to modify the ocular signs, much larger doses are needed to sustain improvement and replenish the depleted thiamine stores—50 mg intravenously and 50 mg intramuscularly—the latter dose being repeated each day until the patient resumes a normal diet.

It should be standard practice in emergency departments to administer 50 to 100 mg of thiamine simultaneously with intravenous fluids that contain glucose in order to avoid precipitating Wernicke disease. It is also good practice to give B vitamins to all alcoholic patients. The chronic alcoholic (or the nonalcoholic with persistent vomiting) exhausts his body stores of thiamine in a matter of 7 or 8 weeks, at which time the administration of glucose may serve to precipitate Wernicke disease or cause an early form of the disease to progress rapidly. The further management of Wernicke disease involves the use of a balanced diet and all the B vitamins, since the patient is usually deficient in more than thiamine alone.

A problem in management may arise once the patient has recovered from Wernicke disease and the amnesic psychosis becomes prominent. As indicated above, only a minority of such patients (less than 20 percent in our series) recover; moreover, the onset of recovery in such patients may be delayed for several weeks or even months, and then it proceeds very slowly over a period of many months. The extent to which the amnesic symptoms will recover cannot be predicted accurately during the acute stages of the illness; one must guard against the premature commitment of the patient to a mental hospital. Interestingly, the alcoholic Korsakoff patient, once more or less recovered, seldom demands alcohol but will drink it if it is offered.

Infantile Wernicke-Beriberi Disease This term designates an acute and frequently fatal disease of infants, which until recently was very common in rice-eating communities of the Far East. It affects only breast-fed infants, usually in the second to the fifth months of life. Acute cardiac symptoms dominate the clinical picture, but neurologic symptoms (aphonia, strabismus, nystagmus, spasmodic contraction of facial muscles, and convulsions) have been described in many cases. This syndrome can be reversed dramatically by the administration of thiamine, so that some authors prefer to call it *acute thiamine deficiency in infants*. In the few neuropathologic studies that have been made of this disorder, changes like those of Wernicke disease in the adult have been described.

Infantile beriberi bears no consistent relationship to beriberi in the mother. Infants of mothers with overt signs of beriberi may be quite normal. Conversely, mothers of infants with beriberi may themselves be free of the disease. The levels of thiamine in the breast milk of such mothers have not been determined, however. The absence of beriberi in the mothers of affected infants suggests that infantile beriberi might be due to a toxic factor in breast milk, but such a factor, if it exists, has never been isolated.

Rarely, the clinical manifestations of beriberi in infancy represent an inherited (autosomal recessive) thiamine-dependent state, responding to the continued administration of massive doses of thiamine ([Mandel et al](#); see also [Table 41-2](#)).

Disorder	Disorder	Therapeutic dose	Diagnostic tests	Neuropathologic abnormalities
Beriberi (B ₁)	Wernicke-Korsakoff syndrome	5-30 mg	Wernicke-Korsakoff syndrome	Cerebellar ataxia
	Infantile beriberi	5-30 mg	Infantile beriberi	Infantile beriberi
	Alcoholic neuropathy	5-30 mg	Alcoholic neuropathy	Alcoholic neuropathy
	Neuropathy of pregnancy	5-30 mg	Neuropathy of pregnancy	Neuropathy of pregnancy
Pyridoxine (B ₆)	Neuropathy	100 mg	Pyridoxine deficiency	Neuropathy
	Infantile convulsions	50-100 mg	Infantile convulsions	Infantile convulsions
Cobalamin (B ₁₂)	Neuropathy	5-30 mg	Cobalamin deficiency	Neuropathy
	Infantile convulsions	500-1000 µg	Infantile convulsions	Infantile convulsions
Folic acid	Neuropathy	10-30 mg	Folic acid deficiency	Neuropathy
	Infantile convulsions	10-30 mg	Infantile convulsions	Infantile convulsions
Biotin	Neuropathy	1-3 mg	Biotin deficiency	Neuropathy
	Infantile convulsions	1-3 mg	Infantile convulsions	Infantile convulsions
Nicotinamide	Neuropathy	1-3 mg	Nicotinamide deficiency	Neuropathy
	Infantile convulsions	1-3 mg	Infantile convulsions	Infantile convulsions

Table 41-2 Vitamin-responsive inherited disorders affecting the nervous system

NUTRITIONAL POLYNEUROPATHY (NEUROPATHIC BERIBERI)

Most physicians in the western world have only a dim notion about beriberi, which they recall as an ill-defined, predominantly cardiac disorder occurring among the rice-eating people of the Orient. In fact, beriberi is a distinct clinical entity that is not confined to any particular part of the world. Essentially it is a disease of the heart

and of the peripheral nerves (which may be affected separately), with or without edema, the latter feature providing the basis for the classic division into “wet” and “dry” forms. The cardiac manifestations range from tachycardia and exertional dyspnea to acute and rapidly fatal heart failure. This last is the most dramatic manifestation of beriberi, but it is uncommon. Here we are concerned with the affection of the peripheral nerves, or *neuropathic beriberi*, as it is designated.

That beriberi is essentially a degenerative disorder of the peripheral nerves was established in the late nineteenth century by the classic studies of the Dutch investigators Eijkman, Pekelharing and Winkler, and Grijns. Only after beriberi gained acceptance as a nutritional disease (this followed Funk’s discovery of vitamins in 1911) was it suspected that the neuropathy of alcoholics was also nutritional in origin. The similarity between beriberi and alcoholic neuropathy was commented upon by several authors, but it was Shattuck, in 1928, who first seriously discussed the relationship of the two disorders. He suggested that “polyneuritis of chronic alcoholism was caused chiefly by failure to take or assimilate food containing a sufficient quantity of vitamin B . . . and might properly be regarded as true beriberi.” Convincing evidence that “alcoholic neuritis” is not due to the neurotoxic effect of alcohol was supplied by Strauss. He allowed 10 patients to continue their daily consumption of whiskey while they consumed a well-balanced diet supplemented with yeast and vitamin B concentrates; the peripheral nerve symptoms improved in every case. Our own observations support Strauss’s contention that alcoholic polyneuropathy is essentially a nutritional disease.

Clinical Features The symptomatology of nutritional polyneuropathy is diverse. In fact, many patients are asymptomatic, and evidence of peripheral nerve affection is found only on clinical or electromyographic examination. In the latter circumstance the neuropathic signs are mild in degree, consisting of thinness and tenderness of the leg muscles, loss or depression of the Achilles reflexes and perhaps of the patellar reflexes, and at times a patchy blunting of pain and touch sensation over the feet and shins.

The majority of patients, however, are symptomatic—weakness, paresthesias, and pain being the usual complaints. The symptoms are insidious in onset and slowly progressive, but occasionally they seem to evolve or to worsen rapidly, over a matter of days. The initial symptoms are usually referred to the distal portions of the limbs and progress proximally if the illness remains untreated. The lower limbs are always affected earlier and more severely than the upper ones. Most often some aspect of motor disability constitutes the chief complaint, but in about one-quarter of the patients the main complaints are pain and paresthesias. The discomfort takes several forms: a dull, constant ache in the feet or legs; sharp and lancinating pains, momentary in duration, like those of tabes dorsalis; sensations of cramping or tightness in the muscles of the feet and calves; or band-like feelings around the legs. Coldness of the feet is a common complaint but is purely subjective. Far more distressing are feelings of heat or “burning” affecting mainly the soles, less frequently the dorsal aspects of the feet. The dysesthesias fluctuate in severity and characteristically are worsened by contactual stimuli, sometimes to the point where the patient cannot walk or bear the touch of bedclothes, despite the relative preservation of motor power. The term *burning feet* has been applied to this syndrome, but it is not particularly apt, since the patient also complains of other types of paresthesia and pain, and these symptoms may involve the hands as well as the feet.

Examination discloses varying degrees of motor, sensory, and reflex loss. As the symptoms suggest, the signs are symmetrical, usually more severe in distal than in proximal portions of the limbs, and often confined to the legs. The disproportionate affection of motor power may be striking, taking the form of a foot and wrist drop; but even in these patients the proximal muscles are usually affected as well (indicated by difficulty in arising from a squatting position). In other patients, all the leg muscles are affected more or less equally, and in a few, weakness appears to be most severe in the proximal muscles. Absolute paralysis of the legs is observed only rarely; immobility due to contractures at the knees and ankles is a more common occurrence. Tenderness of muscles on deep pressure is a highly characteristic finding, elicited most readily in the muscles of the feet and calves. Deep tendon reflexes in the legs are almost always lost, even when weakness is slight in degree. In the arms, tendon reflexes are sometimes retained despite a loss of strength in the hands. In a small number of patients, particularly those in whom pain and dysesthesias are prominent and motor loss is slight, the reflexes at knee and ankle may be retained or even of greater than average briskness.

Excessive sweating of the soles and dorsal aspects of the feet and of the volar surfaces of the hands and fingers is a common manifestation of alcohol-induced nutritional neuropathy. Postural hypotension is sometimes associated. These symptoms are indicative of involvement of the peripheral sympathetic nerve fibers.

Sensory loss or impairment may involve all the modalities, although one may be affected out of proportion to the others. One cannot predict from the patient’s symptoms which mode of sensation might be affected disproportionately. In patients with impairment of superficial sensation (i.e., touch, pain, and temperature), the border between impaired and normal sensation is not sharp but shades off gradually over a considerable vertical extent of the limbs.

Patients in whom pain is the outstanding symptom do not constitute a distinct group in terms of their neurologic signs. Pain and dysesthesias may be prominent in patients with either severe or slight degrees of motor, reflex, and sensory loss. The term *hyperesthetic* is used commonly to designate the exquisitely painful form of neuropathy but is not well chosen; as pointed out on page 145, one is usually able, by using finely graded stimuli, to demonstrate an elevated threshold to painful, thermal, and tactile stimuli in the “hyperesthetic” zone. Once the stimulus is perceived, however, it has a painful and diffuse, unpleasant quality (hyperpathia). Tactile evocation of pain or burning is an example of allodynia.

In most patients with nutritional polyneuropathy, only the limbs are involved; the abdominal, thoracic, and bulbar muscles are usually spared. In the most advanced instances of neuropathy, hoarseness and weakness of the voice and dysphagia due to affection of the vagus nerves may be added to the clinical picture.

Some idea of the incidence of the motor, reflex, and sensory abnormalities and the combinations in which they occur can be obtained from [Table 41-1](#), which is based on our study of 189 nutritionally depleted alcoholic patients. Noteworthy is the fact that only 66 (35 percent) of the 189 patients showed the clinical picture of polyneuropathy in its entirety—i.e., a symmetrical impairment or loss of tendon reflexes, sensation, and motor power affecting legs more than the arms and the distal more than the proximal segments of the limbs. In the remaining patients, the motor-reflex-sensory signs occurred in various combinations, as indicated in [Table 41-1](#).

Neuropathic abnormality	Legs (189 cases)	Arms (57 cases)
Loss of reflexes alone	45 (24) ^a	6 (10) ^b
Loss of sensation alone	10 (5)	10 (18)
Weakness alone	—	5 (9)
Weakness and sensory loss	2 (1)	10 (18)
Reflex and sensory loss	40 (21)	2 (3)
Sensory, motor, and reflex loss	66 (35)	17 (30)
Data incomplete	26 (14)	7 (12)

^aFigures in parentheses indicate percent of 189 cases.
^bFigures in parentheses indicate percent of 57 cases.

Table 41-1 Clinical findings in nutritional polyneuropathy

Stasis edema and pigmentation, glossiness, and thinness of the skin of the lower legs and feet are common findings in patients with severe forms of neuropathy. Major dystrophic changes, in the form of perforating plantar ulcers and painless destruction of the bones and joints of the feet (ulcero-osteolytic neuropathy; “Charcot forefeet”), have been described but are rare. Repeated trauma to insensitive parts and superimposed infection are thought to be responsible for the neuropathic arthropathy.

The CSF is usually normal, although a modest elevation of protein content is found in a small number of cases. Electromyographic (EMG) findings include mild to moderate degrees of slowing of motor and sensory conduction and a marked reduction of the amplitudes of sensory action potentials; the motor conduction velocities in distal segments of the nerves may be reduced, while conduction in proximal segments is normal. Denervated muscles show fibrillation potentials.

Pathologic Features The essential pathologic change is one of axonal degeneration, with destruction of both axon and myelin sheath. Segmental demyelination may also occur, but only in a small proportion of fibers. This change may be difficult to discern in myelin-stained sections of whole nerve trunks, but it can be observed in teased nerve fibers stained with osmium. The most pronounced changes are observed in the distal parts of the longest and largest myelinated fibers in the crural and, to a lesser extent, brachial nerves. In advanced cases the degenerative changes extend into the anterior and posterior nerve roots. The vagus and phrenic nerves and paravertebral sympathetic trunks may be affected in advanced cases.

Anterior horn and dorsal root ganglion cells undergo chromatolysis, indicating axonal damage. Degenerative changes in the posterior columns are seen in some cases and are probably secondary to the changes in the dorsal spinal roots.

Pathophysiology The nutritional factor(s) responsible for the neuropathy of alcoholism and beriberi have not been defined precisely. Because of the difficulties in producing peripheral neuropathy in Mammalia by means of a thiamine-deficient diet, several investigators in the past questioned the idea that thiamine is the antineuritic vitamin. Very few of the animal experiments undertaken to settle this point are satisfactory from a nutritional and pathologic point of view. Nevertheless, several studies in birds and humans do indeed indicate that uncomplicated thiamine deficiency may result in peripheral nerve disease. The necessity of either accepting or rejecting the specific role of thiamine became less urgent when it was demonstrated, in both animals and humans, that a deficiency of pyridoxine or of pantothenic acid could also result in degeneration of the peripheral nerves (see [Swank and Adams](#)).

The question of whether polyneuropathy in the alcoholic patient might be due to the direct toxic effects of alcohol and not to a nutritional deficiency has been raised from time to time (see, for example, Denny-Brown and Behse and Buchthal). The evidence for this view is not compelling, either on clinical or on experimental grounds (see reference to [Strauss](#), in introductory section on nutritional neuropathy). The interested reader will find a detailed critique of this subject in the chapters by Victor and by Windebank in the second and third editions, respectively, of *Peripheral Neuropathy*, edited by Dyck and coworkers.

Treatment and Prognosis The first consideration is to supply adequate nutrition in the form of a balanced diet supplemented with B vitamins. Equally important is to make certain that the patient follows the prescribed diet. If persistent vomiting or other gastrointestinal complications prevent the patient from eating, then parenteral feeding becomes necessary; the vitamins may be given intramuscularly or added to intravenous fluids.

Where pain and sensitivity of the feet are the major complaints, the pressure of bedclothes may be avoided by placing a cradle support over the legs. Aching of the limbs may be related to their immobility, in which case they should be moved passively on frequent occasions. Aspirin or acetaminophen is usually sufficient to control hyperpathia; occasionally codeine in doses of 15 to 30 mg must be added. Obviously, opiates and addicting synthetic analgesics should be avoided. Some of our patients with severe burning pain (similar to causalgia) in the feet have been helped by blocking the lumbar sympathetic ganglia or by epidural injection of analgesics. The response to phenytoin and carbamazepine (Tegretol) has been inconsistent. Adrenergic blocking medication has been of little value.

The regeneration of peripheral nerves, which may take many months, will be of no avail if the muscles have been allowed to undergo contracture and the joints to become fixed. The patient's legs should be positioned so that the soles rest firmly against a footboard, in order to prevent shortening of the heel cords. In cases of severe paralysis, molded splints should be applied to the arms, hands, legs, and feet during periods of rest. Pressure on the heels and elbows can be avoided by padding the splints and by turning the patient frequently or by asking the patient to do so. As soon as the patient's general condition permits, the limbs must be passively moved through a full range of movement several times daily. As function returns, more vigorous physiotherapeutic measures can be undertaken.

Recovery from nutritional polyneuropathy is a slow process. In the mildest cases there may be a considerable restoration of motor function in a few weeks. In severe forms of the disease, several months may pass before the patient is able to walk unaided. The slowness of recovery creates a special problem for the alcoholic patient, in whom the great danger to continued recovery is the resumption of drinking. Suitable arrangements must therefore be made for close supervision during the long and tedious convalescence.

Deficiency Amblyopia (Nutritional Optic Neuropathy)

("Tobacco-Alcohol Amblyopia"; See also [Chap. 13](#))

These terms refer to a characteristic form of visual impairment that results from nutritional deficiency. The defect in vision is due not to an abnormality of the cornea or other parts of the refractive mechanism but to a lesion of the optic nerve, more or less confined to the region of the papillomacular bundle.

Typically, the patient complains of dimness or blurring of vision for near and distant objects, evolving gradually over a period of several days or weeks. Examination discloses a reduction in visual acuity due to the presence of central or centrocecal scotomata, which are larger for colored than for white test objects. Pallor of the temporal portion of the optic disc is observed in some cases. These abnormalities are bilateral and roughly symmetrical and, if untreated, may progress to blindness and irreversible optic atrophy. With nutritious diet and vitamin supplements, improvement occurs in all but the most chronic cases, the degree of recovery depending upon the severity of the amblyopia and particularly upon its duration before therapy is instituted.

Although the precise deficiency responsible cannot be named, the nutritional basis of this disorder was established beyond doubt during World War II and the Korean War, when innumerable instances were observed in prisoners of war who had been confined for prolonged periods under conditions of severe dietary deprivation. Fisher described the optic nerve lesions in 4 such patients who had died of unrelated causes between 8 and 10 years after the onset of amblyopia. The optic nerves in each case showed a loss of myelin and axis cylinders restricted to the region of the papillomacular fibers. Of the 4 cases, 3 also showed demyelination of the posterior columns of the spinal cord, no doubt an expression of the associated sensory polyneuropathy.

In the western world, a visual disorder indistinguishable clinically and pathologically from that observed in prisoners of war is observed infrequently, mainly among undernourished alcoholics. For many years this has been referred to as *tobacco-alcohol amblyopia*, with the implication that the visual loss is due to the toxic effects of alcohol, tobacco, or both. Actually, the evidence is overwhelming that so-called tobacco-alcohol amblyopia is due to nutritional deficiency. A specific nutrient has not been identified, however. There is evidence in humans and in animals that under certain conditions a deficiency of one or more of the B vitamins—thiamine, vitamin B₁₂, and perhaps riboflavin—may cause degenerative changes in the optic nerves, a situation that pertains in the peripheral nerves as well.

In the 1960s, a popular theory held that the combined effects of vitamin B₁₂ deficiency and chronic poisoning by cyanide (generated in tobacco smoke) were responsible for "tobacco amblyopia." Vitamin B₁₂ deficiency is a rare but undoubted cause of optic neuropathy (page 263), but the notion that cyanide or other substances in tobacco smoke have a damaging effect upon the optic nerves is supported neither by logic nor by experimental data (see reviews of [Potts and of Victor](#)). Clinically, instances of Leber's hereditary optic atrophy may be mistaken for "tobacco-alcohol amblyopia"—an error that should no longer be made because the former disorder can now be identified with certainty by mitochondrial DNA testing.

The most recent outbreaks of nutritional optic neuropathy occurred in Cuba during 1991–1993 and in Tanzania. In both outbreaks the optic neuropathy was frequently associated with peripheral neuropathy, for which reason they are considered further on, with the Strachan syndrome.

Pellagra

In the early 1900s, pellagra attained epidemic proportions in the southern United States and in the alcoholic population of large urban centers. Since 1940, the prevalence of pellagra has diminished greatly because of the general practice of enriching bread with niacin. Nevertheless, among the vegetarian, maize-eating people of underdeveloped countries and among the black population of South Africa, pellagra is still a common disease ([Bomb et al](#), [Shah et al](#), [Ronthal and Adler](#)). In developed countries, pellagra is practically confined to alcoholics ([Ishii and Nishihara](#), [Spivak and Jackson](#), [Serdaru et al](#)).

In its fully developed form, pellagra affects the skin, alimentary tract, and hematopoietic and nervous systems. The early symptoms may be mistaken for those of a neurosis. Insomnia, fatigue, nervousness, irritability, and feelings of depression are common complaints; examination may disclose mental dullness, apathy, and an impairment of memory. Sometimes an acute confusional psychosis dominates the clinical picture. Untreated, these symptoms may progress to a dementia. Pellagra may not only produce insanity but occasionally result from it, by virtue of the anorexia and refusal of food that accompany certain mental illnesses. The *spinal cord* manifestations have not been clearly described; in general, the signs are referable to both the posterior and lateral columns, predominantly the former. Signs of *peripheral nerve affection* are relatively less common and are indistinguishable from those of neuropathic beriberi.

Pathologic Changes These are most readily discerned in the large cells of the motor cortex, the cells of Betz and are seen to a lesser extent in the smaller pyramidal cells of the cortex, the large cells of the basal ganglia, the cells of the cranial motor and dentate nuclei, and the anterior horn cells of the spinal cord. The affected cells appear swollen and rounded, with eccentric nuclei and loss of the Nissl bodies (frequently referred to as "axonal reaction"). In the pathologic material of Hauw and associates, the chromatolytic changes were most pronounced in the brainstem nuclei (upper reticular and pontine) and not in the Betz cells. They concluded that

these changes were not due to a retrograde axonal lesion, but did not comment on the status of the spinal cord.

The spinal cord lesions in pellagra take the form of a symmetrical degeneration of the dorsal columns, especially of Goll, and to a lesser extent of the corticospinal tracts. Such a posterior column degeneration, affecting a specific system of fibers, is likely to be secondary to degeneration of the dorsal root ganglion cells or posterior roots. The reason for the corticospinal tract degeneration is not clear. The few studies of the peripheral nerves in pellagra have disclosed changes like those in alcoholics and other patients with nutritional deficiency.

Etiology It has been known since 1937, when Elvehjem and coworkers showed that nicotinic acid cured black tongue, a pellagra-like disease in dogs, that this vitamin is effective in the treatment of pellagra. Many years before, Goldberger had demonstrated the curative effects of dietary protein and proposed that pellagra was caused by a lack of specific amino acids (see [Terris](#)). Now it is known that pellagra may result from a deficiency of either nicotinic acid or tryptophan, the amino acid precursor of nicotinic acid. One milligram of nicotinic acid is formed from 60 mg of tryptophan, a process for which pyridoxine is essential. This explains the frequent occurrence of pellagra in persons who subsist mainly on corn, which contains only small amounts of tryptophan and niacin—some of the niacin being in bound form and unavailable for absorption.

It should be pointed out that in experimental subjects, only the cutaneous-gastrointestinal-neurasthenic manifestations of pellagra have been produced by the feeding of tryptophan- or niacin-deficient diets; neurologic abnormalities were not produced by these diets ([Goldsmith](#)). As a corollary, only the dermal, gastrointestinal, and neurasthenic manifestations respond to treatment with niacin and tryptophan; neurologic disturbances in pellagrins have proved to be recalcitrant to prolonged treatment with nicotinic acid, although the peripheral nerve disorder may subsequently respond to treatment with thiamine. In monkeys, degeneration of peripheral nerves as well as the unique cerebrocortical changes of pellagra were induced by a deficiency of pyridoxine ([Victor and Adams](#), 1956). Swank and Adams described degeneration of the peripheral nerves in pyridoxine- and pantothenic acid–deficient swine, and Vilter and colleagues produced polyneuropathy in human subjects rendered pyridoxine-deficient; these subjects also showed seborrheic dermatitis and glossitis (indistinguishable from that of niacin deficiency) and the cheilosis and angular stomatitis that are usually attributed to riboflavin deficiency. The foregoing observations indicate that certain lingual and cutaneous manifestations of pellagra may be produced by a deficiency of pyridoxine or other B vitamins and that the neurologic manifestations of pellagra are most likely due to pyridoxine deficiency.

In the special case of Hartnup disease, a niacin deficiency is believed to result from the high excretion of indicans and indole metabolites (see page 1009).

Nutritional Spinal Spastic and Ataxic Syndrome This syndrome is observed occasionally in nutritionally depleted alcoholics. The main clinical signs are spastic weakness of the legs, with absent abdominal and increased tendon reflexes, clonus, extensor plantar responses, and a loss of position and vibratory senses. In our experience, this syndrome is usually associated with other nutritional disorders, such as Wernicke disease and peripheral and optic neuropathy. In prisoner-of-war camps, the “spastic syndrome” was observed in association with mental and emotional changes and dimness of vision, and at times with widespread muscular rigidity, confusion, coma, and death. The latter syndrome has never been studied pathologically, so that it is impossible to state whether the lesions are the same as or different from those of pellagra.

The syndromes of tropical spastic paraparesis and of lathyrism, another form of spastic paraplegia that is common in India and certain parts of Africa, were for many years suspected of being nutritional in origin but are now known to be due to a virus and to a toxin, respectively. These and other types of tropical spastic paraplegia are discussed in greater detail with the spinal cord diseases ([Chap. 44](#)). A chronic tropical disease of the peripheral nerves, designated as “ataxic neuropathy of Nigeria,” has been attributed to the ingestion of inadequately detoxified cassava ([Osuntokun](#)).

Nicotinic Acid Deficiency Encephalopathy Under this title, Jolliffe and coworkers, in 1940, described an acute cerebral syndrome in alcoholic patients consisting of clouding of consciousness, progressing to extrapyramidal rigidity and tremors (“cogwheel” rigidity) of the extremities, uncontrollable grasping and sucking reflexes, and coma. Most of their patients showed overt manifestations of nutritional deficiency, such as Wernicke disease, pellagra, scurvy, and polyneuropathy. These authors concluded that the encephalopathy represented an acute form of nicotinic acid deficiency, since most of their patients recovered when treated with a diet of low vitamin B content supplemented by intravenous glucose and saline and large doses of nicotinic acid. Sydenstricker and colleagues (1938) had previously reported the salutary effects of nicotinic acid on the unresponsive state observed in elderly undernourished patients, and [Spillane \(1947\)](#) described a similar syndrome and response to nicotinic acid in the indigent Arab population of the Middle East.

The status of this syndrome and its relation to pellagra are uncertain. The clinical, nutritional, and pathologic features were never delineated precisely. Serdaru and associates reported 22 presumed examples of this syndrome in the alcoholic population of the Salpêtrière clinic in Paris, all reviewed retrospectively after the finding, in postmortem material, of pellagra-like changes in nerve cells. Prominent were confusional states, oppositional rigidity (gegenhalten), ataxia, and polymyoclonia—a picture somewhat like that described by Jolliffe and coworkers (above). Skin lesions were absent. We have not encountered identical cases among the undernourished patients in the alcoholic populations of Boston and Cleveland.

Syndrome of Amblyopia, Painful Neuropathy, and Orogenital Dermatitis (“Strachan Syndrome”)

There remains to be considered a neurologic syndrome that almost certainly is nutritional in origin but does not conform clinically to beriberi and pellagra, the classic deficiency diseases. This syndrome was originally observed by Strachan in 1897 among Jamaican sugar cane workers. The main symptoms in his patients were pain, numbness, and paresthesias of the extremities; objectively there was ataxia of gait, weakness, wasting, and loss of deep tendon reflexes and sensation in the limbs. Dimness of vision and impairment of hearing were common findings, as were soreness and excoriation of the mucocutaneous junctions of the mouth. This disorder, originally known as “Jamaican neuritis,” was quickly recognized in other parts of the world, particularly in the undernourished populations of tropical countries. Subsequently, many cases of this syndrome were observed in the besieged population of Madrid during the Spanish Civil War and during World War II among prisoners of war in North Africa and the Far East.

As indicated earlier, a massive outbreak of a similar disorder, affecting more than 50,000 persons, occurred in Cuba from late 1991 through 1993. The association of this epidemic with widespread dietary deprivation and the salutary response of both optic and peripheral nerve symptoms to treatment with B vitamins suggests a nutritional causation (see [Morbidity and Mortality Weekly Report](#) and the report of the Cuba Neuropathy Field Investigation Team, cited in the References). Shortly thereafter, Plant and colleagues reported on a similar outbreak of optic and peripheral neuropathy from Tanzania.

The clinical descriptions from these varied sources are not entirely uniform, but certain features are common to all of them, and others occur with sufficient frequency to allow the delineation of a neurologic syndrome and its identification with the one described by Strachan. The core disorder is an affection of the peripheral and optic nerves. The former consists mainly of sensory symptoms and signs, and the latter is characterized by the subacute evolution of failing vision, which, if untreated, may go on to complete blindness and pallor of the optic discs. Deafness and vertigo are generally uncommon, but in some outbreaks among prisoners of war these symptoms were frequent enough to earn the epithet “camp dizziness.” In all these respects the syndrome differs from beriberi. Along with the neurologic signs there may be varying degrees of stomatoglossitis, corneal degeneration, and genital dermatitis (the orogenital syndrome). These mucocutaneous lesions are unlike those of pellagra.

There have been only a few neuropathologic studies of this syndrome. Aside from the changes in the papillomacular bundle of the optic nerve, the most consistent abnormality has been a loss of medullated fibers in each column of Goll adjacent to the midline. Fisher has interpreted this change to indicate a degeneration of the central processes of the bipolar sensory neurons of the dorsal root ganglia. The fact that the primary sensory neuron is the main site of the neuropathic disorder is consistent with the predominantly sensory symptomatology. The present authors find it difficult to draw a sharp dividing line between the nutritional peripheral (and optic) neuropathy and the Strachan syndrome.

The Neurologic Manifestations of Vitamin B₁₂ Deficiency

The spinal cord, brain, optic nerves, and peripheral nerves may all be affected by vitamin B₁₂ (cobalamin) deficiency. The spinal cord is usually affected first and often exclusively. The term *subacute combined degeneration* (SCD) is customarily reserved for the spinal cord lesion of vitamin B₁₂ deficiency and serves to distinguish it from other types of spinal cord disease that happen to involve the posterior and lateral columns (loosely referred to as *combined system disease*). Whether the peripheral neuropathy is a primary component of the disease or is secondary to damage of the fibers of entry or exit in the cord has been debated, but the available pathologic evidence favors the former.

The hematologic effects of vitamin B₁₂ deficiency—i.e., *pernicious anemia*—and its neurologic manifestations are distinctive insofar as they result not from a dietary

lack of vitamin B₁₂ but from the failure to transfer minute amounts of this nutrient across the intestinal mucosa—“starvation in the midst of plenty,” as Castle aptly put it. This failure derives from the chronic absence of an intrinsic factor, which is secreted (along with hydrochloric acid) by the parietal cells of the gastric mucosa and which transports cobalamin (extrinsic factor in the diet) to the ileum, where it is absorbed into the portal system. This is referred to as a *conditioned deficiency*, since it is conditional upon the lack of an intrinsic factor.

The hematologic and neurologic manifestations of vitamin B₁₂ deficiency occasionally complicate other malabsorptive disorders: celiac sprue; extensive gastric or ileal resections; overgrowth of intestinal bacteria in “blind loops,” anastomoses, diverticula, and other conditions resulting in intestinal stasis; and infestation with cobalamin-metabolizing fish tapeworm (*Diphyllobothrium latum*). Rare instances of vitamin B₁₂ deficiency are observed in lactovegetarians, in infants nursed by mothers deficient in vitamin B₁₂, and as a result of nitrous oxide poisoning. Finally, vitamin B₁₂ deficiency may be due to a rare genetic defect of methylmalonyl coenzyme A (CoA) mutase ([Table 41-2](#)).

Clinical Manifestations Symptoms of nervous system disease occur in the majority of patients with pernicious anemia. The patient first notices general weakness and paresthesias consisting of tingling, “pins and needles” feelings, or other vaguely described sensations. The paresthesias involve the hands and feet, more often the former, and tend to be constant and steadily progressive and the source of much distress. As the illness progresses, the gait becomes unsteady and stiffness and weakness of the limbs, especially of the legs, develop. If the disease remains untreated, an ataxic paraplegia evolves, with variable degrees of spasticity and contracture.

Early in the course of the illness, when only paresthesias are present, there may be no objective signs. Later, examination discloses a disorder of the posterior and lateral columns of the spinal cord, predominantly of the former. Loss of vibration sense is by far the most consistent sign; it is more pronounced in the feet and legs than in the hands and arms and frequently extends over the trunk. Position sense is usually impaired as well. The motor signs, usually limited to the legs, include a mild symmetrical loss of strength in proximal limb muscles, spasticity, changes in tendon reflexes, clonus, and extensor plantar responses. At first the patellar and Achilles reflexes are found to be diminished as frequently as they are increased, and they may even be absent. With treatment the reflexes may return to normal or become hyperactive. The gait at first is predominantly ataxic, later ataxic and spastic.

Loss of superficial sensation below a segmental level on the trunk may occur in isolated instances, implicating the spinothalamic tracts, but such a finding should always suggest the possibility of some other disease of the spinal cord. The defect of cutaneous sensation may take the form of impaired tactile, pain, and thermal sensation over the limbs in a distal distribution, implicating the peripheral nerves, but such findings are also relatively uncommon. The Lhermitte phenomenon (paresthesias down the spine or across the shoulders induced by rapid flexion of the neck) is a not uncommon finding if sought.

The nervous system involvement in subacute combined degeneration is roughly symmetrical, and sensory disturbances precede the motor ones; predominantly motor involvement from the beginning and a definite asymmetry of motor or sensory findings maintained over a period of weeks or months should always cast doubt on the diagnosis.

Mental signs are frequent, ranging from irritability, apathy, somnolence, suspiciousness, and emotional instability to a marked confusional or depressive psychosis or intellectual deterioration. Lindenbaum and coworkers have reported cases in which neuropsychiatric symptoms, responsive to vitamin B₁₂, were present without spinal cord or peripheral nerve abnormalities. In our clinical material, symptoms of dementia have not been frequent and always followed the spinal cord disorder. *Visual impairment* due to optic neuropathy may occasionally be the earliest or sole manifestation of pernicious anemia; examination discloses roughly symmetrical centrocecal scotomata and optic atrophy in the most advanced cases (page 263). The fact that visual evoked potentials may be abnormal in vitamin B₁₂-deficient patients without clinical signs of visual impairment suggests that the visual pathways may be affected more often than is evident from the neurologic examination alone. A small number of patients have symptoms of autonomic dysfunction, including urinary sphincteric symptoms and impotence.

The CSF is usually normal; in some cases there is a moderate increase in protein. The EMG shows slowing of sensory conduction or reduced-amplitude sensory potentials. Almost always, according to Hemmer and colleagues, somatosensory evoked potentials show delayed conduction or absent responses; these changes are known to recover with treatment. Quite remarkable, as these authors report, is the finding on MRI of a T2 signal change that demarcates the posterior columns of the cord ([Fig. 41-1](#)).

Figure 41-1 Sagittal spinal MRI, T2-weighted image in subacute combined degeneration showing signal changes in the posterior columns. The patient had markedly reduced vibration and position sense and a Romberg sign; the tendon reflexes were preserved and there were no corticospinal tract or peripheral nerve signs. (Courtesy of Dr. James Corbett.)

Neuropathologic Changes The pathologic process takes the form of a diffuse though uneven degeneration of white matter of the spinal cord and occasionally of the brain. The earliest histologic event is a swelling of myelin sheaths, characterized by the formation of intramyelinic vacuoles and separation of myelin lamellae. This is followed by a coalescence of small foci of tissue destruction into larger ones, imparting a vacuolated, sieve-like appearance to the tissue—an appearance also observed commonly in the myelopathy of AIDS and rarely in lupus erythematosus. The myelin sheaths and axis cylinders are both involved in the degenerative process, the former more obviously and perhaps earlier than the latter. There is relatively little fibrous gliosis in the early lesions, but in more chronic ones, particularly those in which considerable tissue is destroyed, the gliosis is pronounced. The changes begin in the posterior columns of the lower cervical and upper thoracic segments of the cord and spread from this region up and down the cord as well as forward into the lateral and anterior columns. The lesions are not limited to specific systems of fibers within the posterior and lateral funiculi but are scattered irregularly through the white matter. For this reason, the term *combined system disease*, which is often used loosely to designate the myelopathy of pernicious anemia, is a less appropriate term than *subacute combined degeneration*.

In rare instances, foci of spongy degeneration are found in the optic nerves and chiasm and in the central white matter of the brain ([Adams and Kubik](#)). The peripheral nerves may show a loss of myelin, but there is no unequivocal evidence that axis cylinders are significantly affected.

It has been shown that monkeys who are sustained on a vitamin B₁₂-deficient diet for a prolonged period develop neuropathologic changes indistinguishable from those of subacute combined degeneration in humans ([Agamanolis et al](#)). The time required for the production of central nervous system changes in monkeys—33 to 45 months—is comparable to the time required to deplete the vitamin B₁₂ stores of patients with pernicious anemia in whom parenteral vitamin B₁₂ therapy had been discontinued. It is noteworthy that vitamin B₁₂-deprived monkeys do not become anemic, despite the prolonged period of vitamin B₁₂ deficiency. Also, in distinction to the human condition, involvement of the optic nerves is particularly severe in the monkey and probably precedes the degeneration of the spinal cord. The optic nerve lesion appears first in the papillomacular bundles, in the retrobulbar portions of the nerves; it subsequently spreads beyond the confines of this bundle and caudally in the optic nerves, chiasm, and tracts. These changes are much the same as those of “tobacco-alcohol amblyopia” (see above). The peripheral nerves were not affected in the experimentally produced vitamin B₁₂ deficiency.

The paresthesias, impairment of deep sensation, and ataxia are due to lesions in the posterior columns, and these may also account for the loss of tendon reflexes. Weakness, spasticity, increased tendon reflexes, and Babinski signs depend on involvement of the corticospinal tracts. The spinothalamic tracts may be involved in the pathologic process, which explains the occasional finding of a sensory level for pain and temperature on the trunk. The distal and symmetrical impairment of

superficial sensation and loss of tendon reflexes that occur in some patients are best explained by involvement of peripheral nerves and are reflected in nerve conduction studies (see further on, under “[Diagnosis](#)”).

Pathogenesis *Methylcobalamin* is an essential cofactor in the conversion of homocysteine to methionine. An impairment of this reaction due to a deficiency of cobalamin is thought to cause a failure of DNA synthesis, accounting for the hematologic abnormalities and particularly for the production of megaloblasts. However, since neurons do not divide, this sequence of chemical events does not explain the central nervous system abnormalities. One of the better-understood functions of vitamin B₁₂ is its role as a coenzyme in the methylmalonyl CoA–mutase reaction. In this reaction, which is a key step in propionate metabolism, methylmalonyl CoA is transformed to succinyl CoA, which subsequently enters the Krebs cycle. A lack or failure of the cobalamin-dependent enzyme methylmalonyl CoA mutase leads to the accumulation of methylmalonyl CoA and its precursor, propionyl CoA. According to this theory, propionyl CoA displaces succinyl CoA, which is the usual primer for the synthesis of even-chain fatty acids and results in the anomalous insertion of odd-chain fatty acids into membrane lipids, such as are found in myelin sheaths. Conceivably this biochemical abnormality underlies the lesions of myelinated fibers that characterize this disease. However, Carmel and associates have described a hereditary form of cobalamin deficiency in which the methylmalonyl CoA mutase activity was normal, despite the presence of typical neurologic abnormalities. In their view, the primary failure is one of methylation of homocysteine to methionine, i.e., a failure of the methionine synthetase reaction, for which the coenzyme methylcobalamin is necessary.

Evidence for the latter view comes also from the observations that prolonged administration of nitrous oxide (N₂O) may produce not only megaloblastic changes in the marrow ([Amess et al](#)) but also a sensorimotor polyneuropathy, often combined with signs of involvement of the posterior and lateral columns of the spinal cord ([Layzer](#)). Probably N₂O produces its effects by inactivating the methylcobalamin-dependent enzyme methionine synthetase. These and other hypotheses are discussed by Jandl, Carmel and colleagues, and Beck.

The role of *folate deficiency* in the genesis of SCD is even less certain. One mistake has been to treat pernicious anemia by giving folic acid; this corrects the anemia but may worsen or even evoke the spinal cord lesions. There are, nevertheless, a few reported examples of cerebral and spinal cord lesions indistinguishable from those due to vitamin B₁₂ deficiency in patients with defective folate metabolism—both in adults with acquired deficiency ([Pincus](#)) and in children with an inborn metabolic error ([Clayton et al](#)).

Diagnosis The main differential diagnostic considerations are cervical spondylosis (page 1322), multiple sclerosis of the cervical cord (page 963), rarities such as the female carrier state of adrenoleukodystrophy (adrenomyeloneuropathy, page 1035), and combined system disease (page 1328). The chief obstacle to *early diagnosis* is the lack of parallelism that may exist between the hematologic and neurologic signs, occurring particularly in patients who have taken dietary or medicinal folate. Anemia may be absent, sometimes for many months, in patients who have not taken folate. In a retrospective study of 141 patients with neuropsychiatric abnormalities due to cobalamin deficiency, there were 19 patients in whom both the hematocrit and mean cell volume were normal ([Lindenbaum et al](#)); in these patients, subtle morphologic abnormalities—hypersegmented polymorphonuclear leukocytes and megaloblastosis in bone marrow smears—were almost always found if carefully sought.

Achlorhydria is almost invariably present in patients with pernicious anemia; its presence can be detected by measuring the serum gastrin level. Antibodies to gastric parietal cells are also present in as many as 90 percent of patients with cobalamin deficiency, but this test often yields false-positive results. The finding of serum antibodies against intrinsic factor is diagnostically specific, but unfortunately they are found in only 60 percent of cases.

Serum cobalamin should be measured whenever the diagnosis of vitamin B₁₂ deficiency is in question. Microbiologic assay (using *Euglena gracilis*) is the most accurate way to measure vitamin B₁₂, but the method is time-consuming and cumbersome and has been largely replaced by a commercial radioisotope dilution assay (the inexpensive chemiluminescence assay is slightly less dependable). With the radioassay, serum levels of less than 100 pg/mL are usually associated with neurologic symptoms and signs of vitamin B₁₂ deficiency. Levels below 200 pg/mL unassociated with symptoms call for further investigation of cobalamin deficiency. Even serum levels of 200 to 300 pg/mL may be associated (in 5 to 10 percent of cases) with cobalamin deficiency. It must be emphasized that the serum cobalamin level is not a measure of total body cobalamin. In a patient who stops absorbing ingested cobalamin, the serum levels may long remain in the normal range despite decreasing tissue reserves. In patients who have received vitamin B₁₂ parenterally, the two-stage Schilling test is a reliable indicator of cobalamin deficiency, since it uncovers a defect in absorption of the vitamin. Low cobalamin levels with or without the clinical signs of deficiency may occur in patients with atrophic gastritis or after subtotal gastrectomy. The malabsorption in such cases is thought to be due to a failure to extract cobalamin from food rather than a failure of the intrinsic-factor mechanism (“food-cobalamin malabsorption”); since the absorption of free cobalamin is normal, the Schilling test is unimpaired ([Carmel](#)). High serum concentrations of cobalamin metabolites—methylmalonic acid (normal range, 73 to 271 nmol/L) and homocysteine (normal range 5.4 to 16.2 mmol/L) are probably the most reliable indicators of an intracellular cobalamin deficiency and can be used to establish the diagnosis ([Allen et al](#); [Lindenbaum et al](#)).

Nerve conduction tests have varied in vitamin B₁₂–deficient patients. Early in the course of SCD, nerve conduction may be normal, but in our experience most patients with neurologic symptoms have slowing of distal sensory conduction; others have found reduced amplitudes and minor signs of denervation, suggestive of axonal change. In patients with normal peripheral nerve studies, the somatosensory evoked potentials show abnormalities that are attributable to central conduction delays, implicating the posterior columns as the cause of the sensory symptoms ([Fine and Hallett](#)). In advanced cases, motor conduction and late responses may be affected to a slight degree. These ambiguities reflect the inconsistent and poorly understood role of the peripheral neuropathic component in this disease.

Treatment The diagnosis of subacute combined degeneration demands the administration of vitamin B₁₂ and the continuation of treatment for the rest of the patient's lifetime. Initially the patient should be given 1000 mg of cyanocobalamin or hydroxycobalamin intramuscularly each day. Thereafter this dose is repeated weekly for a month and then monthly for the remainder of the patient's life. Although most of the injected cobalamin is excreted, these patients must be flooded with the vitamin, because the repletion of cobalamin stores is a direct function of the dose.

The most important factor influencing the response to treatment is the duration of symptoms before treatment is begun; age, sex, and the degree of anemia are relatively unimportant factors. The greatest improvement occurs in those patients whose disturbance of gait has been present for less than 3 months, and recovery may be complete if therapy is instituted within a few weeks after the onset of symptoms. In practically all instances, there is some degree of improvement after treatment, although sometimes, in cases of longest duration, the best that can be accomplished is an arrest of progression. All neurologic symptoms and signs may improve, mostly during the first 3 to 6 months of therapy, and then, at a slower tempo, during the ensuing year or even longer.

Other Neurologic Disorders due to B Vitamin Deficiencies

Pyridoxine (Vitamin B₆) Deficiency A special type of nutritional polyneuropathy is encountered in tuberculous patients as a complication of treatment with isonicotinic acid hydrazide (INH; isoniazid). In the recent past, a similar neuropathy was observed in hypertensive patients treated with hydralazine.

The occurrence of a neuropathy due to INH was recognized in the early 1950s, soon after the introduction of this drug for the treatment of tuberculosis. The neuropathy was characterized by paresthesias and burning pain of the feet and legs, followed by weakness of these parts and loss of ankle reflexes. Rarely, with continued use of the drug, the hands were affected as well. The nature of INH-induced neuropathy was clarified by Biehl and Vilter. They found that the administration of isoniazid results in a marked excretion of pyridoxine, and that the administration of pyridoxine in conjunction with INH prevents the development of neuropathy. As a result of this simple preventive measure, very few examples of INH-induced neuropathy are now observed. Hydralazine, closely related in structure to INH, causes the formation of pyridoxal-isoniazid complexes (hydrazones), which makes pyridoxal (the main form of vitamin B₆) unavailable to the tissues. The neuropathy responds favorably to discontinuation of the drug and the administration of pyridoxine.

Pyridoxine deficiency in animals and humans also causes *seizures*. This was first observed in swine by Swank and Adams and later in infants who were maintained on a milk formula lacking in pyridoxine.

Paradoxically, the *consumption of large amounts of pyridoxine* (by food and vitamin faddists) may also cause a *peripheral neuropathy* ([Schaumburg et al](#); [Albin et al](#)). There is no weakness; the symptoms, including ataxia, are purely sensory and can be quite disabling. Improvement is the rule when the drug is withdrawn. This disorder is probably due to the direct toxic effect of pyridoxine on dorsal root ganglion cells.

Pantothenic Acid Deficiency A predominantly sensory neuropathy has also been induced, again in swine, by Swank and Adams and later in humans by a deficiency of pantothenic acid (a constituent of coenzyme A), as reported by [Bean et al](#). In some patients the administration of pantothenic acid has allegedly reversed the

painful dysesthesias of the “burning foot” syndrome.

Riboflavin Deficiency Whether or not riboflavin deficiency leads to neurologic symptoms has been controversial. In the past, there were claims that glossitis, cheilosis, and neuropathy were due to riboflavin deficiency, but its effects were never isolated. Antozzi and coworkers have reported that a metabolic disorder similar to the Reye syndrome can be caused by riboflavin deficiency and corrected by administration of riboflavin alone. The affected infants were hypoglycemic, hypotonic, and episodically weak and unresponsive. Antozzi and colleagues also recorded instances of disease in older children and adults manifesting as a lipid storage polymyopathy due to either a deficiency or malabsorption of riboflavin. Presumably a disorder of flavin metabolism caused an impairment of both beta oxidation of fatty acids and respiratory chain I and II complexes. Serum creatine phosphate was normal in these individuals, but carnitine was reduced. The oral administration of 200 mg of riboflavin and 4 g of carnitine per day relieved the symptoms. We have had no experience with such cases.

In summary, polyneuropathy may be caused by a deficiency of at least four B vitamins—thiamine, pyridoxine, pantothenic acid, and vitamin B₁₂. That a deficiency of riboflavin causes lesions of the central or peripheral nervous system has not been proved. Despite the frequency of folic acid deficiency and its hematologic effects, its role in the pathogenesis of nervous system disease has not been established beyond doubt (see reviews by [Crellin et al](#) and by [Carney](#)).

The polyneuropathy that occasionally complicates the chronic administration of phenytoin has been attributed, on uncertain grounds, to folate deficiency. Botez and colleagues have described a group of 10 patients with sensorimotor polyneuropathy (4 also had spinal cord disease) presumably due to intestinal malabsorption; all of the patients improved over several months while receiving large doses of folic acid. This experience is unique, however. The possible role of folate deficiency in the pathogenesis of spinal cord disease has been mentioned above in relation to vitamin B₁₂ deficiency, and its putative role in psychiatric disease has been discussed by Carney.

Disorders Due to Deficiencies of Fat-Soluble Vitamins

Vitamin E Deficiency A rare neurologic disorder of childhood, consisting essentially of spinocerebellar degeneration in association with polyneuropathy and pigmentary retinopathy, has been attributed to a deficiency of vitamin E consequent upon prolonged intestinal fat malabsorption ([Muller et al](#); [Satya-Murti et al](#)). The same mechanism has been proposed to explain the neurologic disorders that sometimes complicate abetalipoproteinemia (page 1021), fibrocystic disease ([Sokol et al](#)), celiac-sprue disease (page 1198), and extensive intestinal resections ([Harding et al](#)). Vitamin E deficiency has also been observed in young children with chronic cholestatic hepatobiliary disease ([Rosenblum et al](#)). Ataxia, loss of tendon reflexes, ophthalmoparesis, proximal muscle weakness with elevated serum creatine kinase, and decreased sensation are the usual manifestations. These symptoms are referable to parts of the nervous system and musculature that are found to be diseased in animals deprived of vitamin E—degeneration of Clark's columns, spinocerebellar tracts, posterior columns, nuclei of Goll and Burdach, and sensory roots ([Nelson et al](#)). Local differences in the natural concentration of vitamin E in various parts of the nervous system and musculature may account for the distribution of the lesions. In affected children, neurologic function improves after long-term daily supplementation with high doses of vitamin E.

In recent years there have been several reports of an inherited form of spinocerebellar degeneration attributable to vitamin E deficiency (“familial isolated vitamin E deficiency”). In these patients, absorption and transport of vitamin E to the liver is normal, but hepatic incorporation of α -tocopherol (the active form of vitamin E) into very low density lipoproteins is defective ([Traber et al](#)). The α -tocopherol transfer protein, which normally is needed for this transport, is thought to be abnormal in these patients and the cause of spinocerebellar disease. The abnormality has been traced to a mutation in the gene for the α -tocopherol transfer protein, located on chromosome 8q ([Gotoda et al](#)). In a sense this is a vitamin deficiency conditioned by genetic mutation.

Vitamins A and D Disorders due to a lack or excess of these fat-soluble vitamins are seen occasionally. Vitamin A deficiency sometimes occurs with malabsorption syndromes, causing impairment of vision. Excess of vitamin A in children may result in the syndrome of *pseudotumor cerebri* (page 667). Vitamin D deficiency is usually associated with hypoparathyroidism or a malabsorption state and leads to proximal muscle weakness and rickets.

DISEASES OF THE NERVOUS SYSTEM OF PROBABLE BUT UNPROVEN NUTRITIONAL ORIGIN

The disorders comprised by this category, as the above title indicates, have only an uncertain causal relationship to nutritional deficiency. They are found mainly in alcoholics, but their relationship to alcohol is probably not fundamental, since each of them has also been observed in nonalcoholic patients. The belief that these disorders are nutritional in origin is based on certain indirect evidence: (1) Usually a prolonged period of undernutrition, associated with a significant loss of weight, precedes the neurologic illness. In such cases as are associated with alcoholism, the amount of alcohol consumed need not be large, but the dietary deprivation is always severe. (2) Examination at the onset of the illness frequently discloses general physical evidence of undernutrition as well as the presence of neurologic disorders of known nutritional etiology. (3) Certain attributes of the neuropathologic changes—namely their subacute evolution, symmetry, and constancy of localization—are precisely the features that characterize neurologic disorders of known nutritional etiology. (4) The same syndromes are observed occasionally in nonalcoholics under conditions of dietary depletion. (5) There is at least a partial response to correction of the nutritional impairment.

“Alcoholic” Cerebellar Degeneration

This term refers to a common and uniform type of cerebellar degeneration in alcoholics. Its incidence is about twice that of Wernicke disease, but, unlike the latter, it is considerably more frequent in men than in women. It is characterized clinically by a wide-based stance and gait, varying degrees of instability of the trunk, and ataxia of the legs, the arms being affected to a lesser extent and often not at all. Nystagmus and dysarthria are infrequent signs. In addition to an ataxic (intention) tremor, there may be a tremor of the fingers or hands resembling one of the two types of parkinsonian tremor but appearing only when the limbs are placed in certain sustained postures. Mauritz and coworkers have demonstrated that the instability of the trunk in these cases consists of a specific 3-Hz rhythmic swaying in the anteroposterior direction; by contrast, patients with lesions of the cerebellar hemispheres show only slight postural instability without directional preponderance.

In most cases, the cerebellar syndrome evolves over a period of several weeks or months, after which it remains unchanged for many years. In others, it develops more rapidly or more slowly, but in these cases also the disease eventually stabilizes. Occasionally, the cerebellar disorder progresses in a saltatory manner, the symptoms worsening in relation to a severe infectious illness or an attack of delirium tremens.

The *pathologic changes* consist of a degeneration of all the neurocellular elements of the cerebellar cortex, but particularly of the Purkinje cells; they are restricted to the anterior and superior aspects of the vermis and, in advanced cases, to the anterior parts of the anterior lobes. The cerebellar atrophy is readily visualized by computed tomography (CT) ([Fig. 41-2](#)) and MRI.

Figure 41-2 CT scan from a 60-year-old alcoholic patient showing prominence of midline cerebellar sulci. A broad-based gait and ataxia of the legs had been present for many years. Death was from myocardial infarction. The cerebellum, cut in the midsagittal plane (below), shows folial atrophy of the anterior-superior vermis, characteristic of alcoholic cerebellar degeneration.

Two particular forms of this syndrome have not been emphasized sufficiently. In one, the clinical abnormalities are limited to an instability of station and gait, individual movements of the limbs being unaffected. The pathologic changes in such cases are restricted to the anterosuperior portions of the vermis. A second type

is acute and transient in nature. Here, except for their reversibility, the cerebellar symptoms are identical to those that characterize the chronic, fixed form of the disease. In this transient type, the derangement is only one of function (“biochemical lesion”) and has probably not progressed to the point of fixed structural changes. These forms of cerebellar disease, and particularly the restricted and reversible varieties, cannot be distinguished from the cerebellar manifestations of Wernicke disease either on pathologic or on clinical grounds. It is our opinion that the cerebellar ataxia of Wernicke disease and that referred to as *alcoholic cerebellar degeneration* represent the same disease process, the former term being applicable when the cerebellar abnormalities are associated with ocular and mental signs and the latter when the cerebellar syndrome stands alone. Alcoholic cerebellar degeneration is in all likelihood due to nutritional deficiency and not to the toxic effects of alcohol or other causes, for reasons already indicated. Insofar as the cerebellar ataxia usually improves to some extent under the influence of thiamine alone (see above, under “[Wernicke-Korsakoff Syndrome](#)”), it is likely that a deficiency of this vitamin is responsible for the cerebellar lesion.

Marchiafava-Bignami Disease (Primary Degeneration of the Corpus Callosum)

In 1903, the Italian pathologists Marchiafava and Bignami described a unique alteration of the corpus callosum in three alcoholic patients. In each case, coronal sectioning of the fixed brain disclosed a pink-gray discoloration of the central portion of the corpus callosum throughout the longitudinal extent of this structure. Microscopically, the lesion proved to be confined to the middle lamina (which makes up about two-thirds of the thickness of the corpus callosum), in which there was a loss of myelin with relative preservation of the axis cylinders; macrophages were abundant in the altered zone, and astrocytic proliferation followed. The clinical observations in these patients were few and incomplete. In 1907, Bignami described a case in which the corpus callosum lesion was accompanied by a similar lesion in the central portion of the anterior commissure.

These early reports were followed by a spate of articles that confirmed and amplified the original clinical and pathologic findings. By 1922 about 40 cases of this disorder had been described in the Italian literature ([Mingazzini](#)). With one exception, all the reported cases were in males, and all of these men were insatiable drinkers. They drank red wine for the most part but other forms of liquor also. Beginning in 1936, with the report of King and Meehan, the disease came to be recognized throughout the world, and the notions that it had a predilection for drinkers of red wine and a special racial predisposition or geographic restriction were abandoned.

Pathologic Features Marchiafava-Bignami disease is more readily defined by its pathologic than by its clinical features. The principal alteration is in the middle portion of the corpus callosum, which on gross examination appears somewhat rarefied and sunken and reddish or gray-yellow in color, depending on its age. In the anterior portion of the corpus callosum, the lesion tends to be more severe in the midline than in its lateral parts; in the splenium, however, the opposite may pertain. The most chronic lesion takes the form of a centrally placed gray cleft or cavity, with collapse of the surrounding tissue and reduction in thickness of the corpus callosum. Microscopically, corresponding to the gross lesions, one observes clearly demarcated zones of demyelination, with variable involvement of the axis cylinders and an abundance of fatty macrophages with gliosis at the margins. Inflammatory changes are absent.

Infrequently, lesions of a similar nature are found in the central portions of the anterior and posterior commissures and the brachia pontis. These zones of myelin destruction are always surrounded by a rim of intact white matter. The predilection of this disease process for commissural fiber systems has been stressed, but it is certainly not confined to these fibers. Symmetrically placed lesions have been observed in the columns of Goll, superior cerebellar peduncles, and cerebral hemispheres, involving the centrum semiovale and extending, in some cases, into the adjacent convolutional white matter. As a rule, the internal capsule and corona radiata, subcortical arcuate fibers, and cerebellum are spared. In several cases, the lesions of deficiency amblyopia (see above) have been observed, and in others, the lesions of Wernicke disease.

Many of the reported cases, as first pointed out by Jequier and Wildi, have involved cortical lesions of a special type: the neurons in the third layer of the frontal and temporal lobe cortices had disappeared and were replaced by a fibrous gliosis. Morel, who first described this *cortical laminar sclerosis*, did not observe its association with Marchiafava-Bignami disease. However, when Jequier and Adams reviewed his original cases (unpublished), all had Marchiafava-Bignami disease. In a subsequent report by Delay and colleagues comprising 14 cases of cortical laminar sclerosis, the cortical lesion was also consistently associated with a corpus callosum lesion. We believe the cortical lesions to be secondary to the callosal degeneration.

Clinical Features The disease affects persons in middle and late adult life. With few exceptions, the patients have been males and severe chronic alcoholics. The clinical features of the illness are otherwise quite variable, and a clear-cut syndrome of uniform type has not emerged. Many patients have presented in a state of terminal stupor or coma, precluding a detailed neurologic assessment. In others, the clinical picture was dominated by the manifestations of chronic inebriation and alcohol withdrawal—tremor, seizures, hallucinosis, and delirium tremens. In some of these patients, following the subsidence of the withdrawal symptoms, no signs of neurologic disease could be elicited, even in the end stage of the disease, which lasted for several days to weeks. In yet another group, a progressive dementia has been described, evolving slowly over a 3- to 6-year period before death. Emotional disorders leading to acts of violence, marked apathy, moral perversions, and sexual misdemeanors have been noted in these patients; dysarthria, slowing and unsteadiness of movement, transient sphincteric incontinence, hemiparesis, and apractic or aphasic disorders were superimposed. The last stage of the disease is characterized by physical decline, seizures, stupor, and coma. An impressive feature of these varied neurologic deficits in some patients has been their tendency toward remission when nutrition was restored.

In two cases that have come to our attention, the clinical manifestations were essentially those of bilateral frontal lobe disease: motor and mental slowness; apathy; prominent grasping and sucking reflexes; gegenhalten; incontinence; and a slow, hesitant, wide-based gait. In both of these cases, the neurologic abnormalities evolved over a period of about 2 months, and both patients recovered from these symptoms within a few weeks of hospitalization. Death occurred several years later as a result of liver disease and subdural hematoma, respectively. In each case, autopsy disclosed an old lesion typical of Marchiafava-Bignami disease confined to the central portion of the most anterior parts of the corpus callosum, but one had to look closely to see the gray line of gliosis.

In view of the great variability of the clinical picture and the obscurity in many patients of subtle mental and neurologic abnormalities by the effects of chronic inebriation and other alcoholic neurologic disorders, the *diagnosis* of Marchiafava-Bignami disease is understandably difficult. In fact, it is rarely made during life. The occurrence, in a chronic alcoholic, of a frontal lobe syndrome or a symptom complex that points to a diagnosis of frontal or corpus callosum tumor but in whom the symptoms remit should suggest the diagnosis of Marchiafava-Bignami disease. The CT scan and MRI have disclosed some unsuspected instances of this disease (see also [Kawamura et al](#)).

Pathogenesis and Etiology Originally, Marchiafava-Bignami disease was attributed to the toxic effects of alcohol, but this is an unlikely explanation in view of the prevalence of alcoholism and the rarity of corpus callosum degeneration. Further, the distinctive callosal lesions have not been observed with other neurotoxins. Very rarely, undoubted examples of Marchiafava-Bignami disease have occurred in abstainers, so that alcohol cannot be an indispensable factor. A nutritional etiology has been invoked, for the reasons given earlier, but the deficient factor has not been defined. The mechanisms involved in the selective necrosis of particular areas of white matter remain to be elucidated. Perhaps, when its mechanism becomes known, Marchiafava-Bignami disease, like central pontine myelinolysis (which it resembles histologically), will have to be considered in a chapter other than one on nutritional disease.

Protein-Calorie Malnutrition (PCM) and Mental Retardation

The reader might gather from the foregoing descriptions that the nervous system is rarely affected by nutritional deficiency except when subjected to the influence of chronic alcoholism, and then the essential problem is one of dietary imbalance—an inadequacy of B vitamins in the face of an adequate or near adequate caloric intake. It is true that the CNS resists the effects of starvation better than other organs. Nonetheless, there is increasing evidence that severe dietary deprivation during critical phases of brain development may result in permanent impairment of cerebral function and in mental retardation. Inasmuch as there are an estimated 100 million children in the world who are undernourished and suffer from varying degrees of protein, calorie, and other dietary inadequacies, this is one of the most pressing problems in medicine and society.

Two overlapping syndromes have been defined in malnourished infants and children: kwashiorkor and marasmus. *Kwashiorkor* is a syndrome of weanling children and is due to protein deficiency; it is manifest by edema (and sometimes ascites), hair changes (sparsity and depigmentation), and stunting of growth. The edema is due to hypoalbuminemia; in addition, there is an abnormal pattern of blood amino acids as well as a fatty liver. Sometimes there are skin changes suggestive of pellagra or riboflavin deficiency. *Marasmus* is characterized by an extreme degree of cachexia and growth failure in early infancy. Infants with marasmus have usually been weaned early or were never breast-fed. Common to both groups of children is an apathy and indifference to the environment combined with irritability when they are handled or moved. The children are underactive; even after an adequate diet has been instituted, their tendency is to follow with the eyes rather than to move. At one stage of early convalescence, some kwashiorkor children pass through a phase of rigidity and tremor for which there has been no explanation.

As a rule, the clinical signs of polyneuropathy or subacute combined degeneration of the cord are lacking in children with PCM. However, electrophysiologic testing

Intemperance in the use of alcohol creates many problems in modern society, the importance of which can be judged by the repeated emphasis they receive in contemporary writings, both literary and scientific. These problems may be divided into three categories: psychologic, medical, and sociologic. The main psychologic problem is why a person drinks excessively, often with full knowledge that such action will result in physical injury and even death. The medical problem embraces all aspects of alcoholic habituation as well as the diseases that result from the abuse of alcohol. The sociologic problem consists of the effects of sustained drinking on the patient's work, family, and community. Some idea of the enormity of these problems can be gleaned from figures supplied by the Secretary of Health and Human Services—which reveal that up to 40 percent of medical and surgical patients have alcohol-related problems and that these patients account for 15 percent of all health care costs (which in 1995 were estimated at 150 billion dollars).

These several problems engendered by excessive drinking cannot be separated from one another; the physician must therefore be conversant with all aspects of this subject. He may be asked to help the patient to overcome his drinking problem or to diagnose and treat the numerous diseases to which such a patient is subject; often he must admit the patient to a “detoxification” unit or a general hospital or to a psychiatric facility, according to the nature of the clinical disorder; and, last, he may be required to enlist the aid of social agencies when their services are needed by either the patient or the patient's family.

Primary alcoholism has been defined as both a chronic disease and a disorder of behavior, characterized in either context by chronic, repetitive, excessive drinking to an extent that interferes with the drinker's health, interpersonal relations, or means of livelihood. Reduced to pharmacologic terms, it is addiction to alcohol. *Secondary alcoholism* refers to excessive drinking in the context of another major psychiatric illness—e.g., manic-depressive disease. The term *alcoholism*, unqualified, refers to the primary variety.

The causation of alcoholism remains obscure, although environmental, cultural, and genetic factors are clearly implicated in certain groups of patients. No single personality type has been shown to predict reliably who will become addicted to alcohol and who will not. Similarly, no particular aspect of alcohol metabolism has been found to account for the development of addiction in some individuals and not in others, with the possible exception of aldehyde dehydrogenase (see below). Some persons drink excessively and become alcoholics in response to some profoundly disturbing personal or family problem, but many do not. Alcoholism may develop in response to a depressive illness, more so in women than in men, but far more often depression is a consequence of drinking. Social and cultural influences are undoubtedly important in the genesis of alcoholism, as evidenced, for example, by the remarkably high incidence of alcoholism and drinking problems in the American Indian and Eskimo populations and by the disparity in the prevalence of alcoholism, within a single community, between the Irish and the Jews. However, no ethnic or racial group and no social or economic class is exempt. Moreover, no particular pattern of child rearing or cultural attitude is universally effective in facilitating or protecting against the development of alcoholism. The writings of Schuckit and of Mello, listed in the references, provide critical overviews of the many etiologic theories.

The importance of genetic factors in the causation of alcoholism is being increasingly recognized. Goodwin and coworkers studied 55 Danish men whose biologic parents were alcoholic and 55 control subjects whose biologic parents were not alcoholic. All of the subjects had been adopted before the age of 5 weeks and had no knowledge of their biologic parentage. Twenty percent of the offspring of biologic alcoholic parents, but only 5 percent of the control subjects, had become alcoholics by the age of 25 to 29 years. A Swedish adoption study ([Bohman](#)) and one in the United States ([Cadoret](#) et al) have corroborated these findings. Family studies have disclosed a three- to fourfold increased risk for alcoholism in sons and daughters of alcoholics, and twin studies have shown a twofold higher concordance rate for alcoholism in monozygotic than in dizygotic pairs. Details of these studies can be found in the comprehensive reviews of the genetics of alcoholism by Grove and Cadoret and by Schuckit. The search goes on for a biologic trait, or marker, that would identify those who are genetically vulnerable to the development of alcoholism, but to date none has proved to be sufficiently practical or sensitive to identify all such persons ([Reich](#)).

As to the frequency of alcoholism, the survey by Grant et al of more than 43,000 households is still an epidemiologic benchmark. They estimated that in 1988, some 15.3 million Americans (8.6 percent of persons 18 years or older) were either alcohol abusers or alcohol- dependent. Of this number, 4.1 million were women. In addition, there were approximately 4.6 million problem drinkers among adolescents (about 20 percent of the persons in this age group). Several more recent surveys have suggested a rate of alcohol dependence of 3 to 5.5 percent of adults. Schuckit has estimated that the lifetime risk for alcoholism is at least 10 percent for men and 3 to 5 percent for women. A minimum of 3 percent of deaths in the United States can be attributed to alcohol-related causes. Alcohol intoxication is responsible for approximately 45 percent of fatal motor vehicle accidents and 22 percent of boating accidents. It requires little imagination to conceive the havoc wrought by alcohol in terms of decreased productivity, increased incidence of suicide, accidents, crime, mental and physical disease, and disruption of family life.

PHARMACOLOGIC AND PHYSIOLOGIC CONSIDERATIONS

Ethyl alcohol, or ethanol, is the active ingredient in beer, wine, whiskey, gin, brandy, and other less common alcoholic beverages. In addition, the stronger spirits contain enanthic ethers, which provide flavor but have no important pharmacologic properties, and impurities such as amyl alcohol (fusel oil) and acetaldehyde, which act like alcohol but are more toxic. Contrary to popular opinion, the content of B vitamins in American beer and other liquors is so low as to have little nutritional value ([Davidson](#)).

Absorption, Distribution, and Metabolism of Alcohol Alcohol is absorbed unaltered from the gastrointestinal tract, about 25 percent from the stomach and the rest from the upper small intestine. Its presence may be detected in the blood within 5 min after ingestion, and the maximum concentration is reached in 30 to 90 min. The ingestion of milk and fatty foods impedes and water facilitates its absorption. The rate of absorption increases after gastrectomy; in such cases maximum blood alcohol concentrations are higher and are attained faster than in persons with intact stomachs. In habituated persons, the blood alcohol concentration rises somewhat faster and reaches a higher maximum than in abstainers. Also in this respect, there may be a difference between the sexes. After consuming comparable amounts of alcohol, women develop higher blood alcohol concentrations than men ([Frezza](#) et al). This effect has been attributed to a diminished “first-pass” metabolism of alcohol in the gastric mucosa, where the alcohol dehydrogenase activity was found to be less in women than it is in men.

Alcohol is carried chiefly in the plasma and enters the various organs of the body—as well as the cerebrospinal fluid (CSF), urine, and pulmonary alveolar air—in concentrations that bear a constant relationship to the concentration in the blood. Alcohol is metabolized chiefly by oxidation, less than 10 percent being excreted chemically unchanged in the urine, perspiration, and breath. The energy liberated by the oxidation of alcohol (7 kcal/g) can be utilized as completely as that derived from the metabolism of other carbohydrates. However, calories from alcohol are empty of nutrients such as proteins and vitamins and cannot be used in the repair of damaged tissue. Therefore, unless the chronic drinker takes an adequate amount of protein (which he frequently fails to do), muscle bulk is lost and other tissues are subject to damage.

All ingested alcohol except that metabolized by alcohol dehydrogenase in the stomach wall is carried by the portal system to the liver. Here several enzyme systems (located in different subcellular compartments of the hepatocyte) can independently oxidize alcohol to acetaldehyde. The most important of these systems, accounting for 80 to 90 percent of ethanol oxidation in vivo, are alcohol dehydrogenase (ADH) and its isoenzymes; they are found in the soluble fraction of the hepatocyte and utilize nicotinamide adenine dinucleotide (NAD) as the cofactor. This reaction leads to the formation of acetaldehyde and the reduction of NAD to NADH. A second pathway involves catalase, which is located in the peroxisomes and mitochondria; a third utilizes the “microsomal ethanol oxidizing system” (MEOS), located mainly in

the microsomes of the endoplasmic reticulum. The MEOS, which is dependent upon reduced nicotinamide adenine dinucleotide phosphate (NADPH), does not account for much of the alcohol metabolized in normal circumstances, but it may be responsible for the increased rate of alcohol metabolism observed in chronic alcoholics.

The aforementioned shift in the NADH/NAD ratio results in a number of metabolic derangements in carbohydrate and lipid metabolism. The synthesis of glucose declines and there is a conversion of lactic to pyruvic acid. However, a significant lowering of blood glucose will occur only if the hepatic glycogen stores are depleted—as a result of fasting, for example. The levels of serum lactate will be increased occasionally, to the point of lactic acidosis. In certain circumstances alcohol can interfere with the peripheral utilization of glucose, resulting in hyperglycemia. Also, as a result of the changed NADH/NAD ratio, there occurs a depression in the oxidation of fatty acids, the excess of which are converted to triglycerides. This leads, in turn, to a fatty liver. Such changes are related to alcohol per se and are independent of malnutrition.

The details of the process by which acetaldehyde is metabolized are still not settled. Most likely it is converted by aldehyde dehydrogenase to acetate. Acetaldehyde has a number of unique biochemical effects that are not produced by alcohol alone. Persons who flush easily after ingestion of alcohol (Chinese, Japanese, and other Asians) differ from “nonflushers” with respect to the metabolism of acetaldehyde rather than to the metabolism of alcohol. The flushing reaction has been traced to a deficiency of aldehyde dehydrogenase activity ([Harada et al](#)). The low rate of alcoholism among Asians is said to be related to the flushing reaction (which is, in effect, a modified alcohol-disulfiram reaction—see further on), but this can hardly be the case, since North American Indians, a group with a high incidence of alcoholism, show the same reaction. There are no valid data to support the claim that acetaldehyde, rather than ethanol itself, is the major intoxicating and addicting agent in alcoholism.

For all practical purposes, it may be accepted that once the absorption of alcohol has ended and an equilibrium has been established with the tissues, *ethanol is oxidized at a constant rate, independent of its concentration in the blood* (about 150 mg alcohol per kilogram of body weight per hour, or about 1 oz of 90-proof whiskey per hour). Actually, slightly more alcohol is metabolized per hour when the initial concentrations are very high, and repeated ingestion of alcohol may facilitate its metabolism, but these increments are of little clinical significance. Neither do agents such as amino acids, insulin, and fructose have any practical value in enhancing ethanol metabolism. On the other hand, the rate of oxidation of acetaldehyde does depend on its concentration in the tissues. This fact is of importance in connection with the drug disulfiram (Antabuse), which acts by raising the tissue concentration necessary for the metabolism of a certain amount of acetaldehyde per unit of time. The patient taking both disulfiram and alcohol will accumulate an inordinate amount of acetaldehyde, resulting in nausea, vomiting, and hypotension, sometimes so pronounced in degree as to be fatal. This pharmacologic principle underlies the treatment of alcoholism with disulfiram. Certain other drugs—notably the sulfonylureas, metronidazole, and furazolidone—have effects like those of disulfiram but are less potent.

The fraction of ingested alcohol that survives first-pass oxidation in the stomach wall and the liver equilibrates rapidly with all bodily tissues and fluids and affects their function to a degree that is governed by the blood alcohol concentration. Only the effects on the nervous system concern us in this chapter. Complete accounts of the nonneurologic effects can be found in the monographs edited by Lieber and by Mendelson and Mello.

Pharmacologic Effects Alcohol acts directly on neuronal membranes in a manner akin to that of the general anesthetics. These agents, as well as barbiturates and benzodiazepines, are lipid-soluble and are thought to produce their effects by dissolving in the cell membranes (in direct relation to the degree of their lipid solubility). This process has a disordering effect on other membrane structures, particularly proteins. With continued ingestion of alcohol, the neuronal membranes rigidify and become resistant to the fluidizing effect of alcohol ([Chin and Goldstein](#); [Harris et al](#)).

It is unlikely, however, that these changes in the physical properties of cell membranes are in themselves sufficient to alter cell function. Probably of greater importance are the effects of alcohol on membrane receptor systems, which regulate ion channels, particularly the chloride and calcium channels. One likely site that relates to the acute intoxicating effects of alcohol is a receptor for the inhibitory neurotransmitter gamma-aminobutyric acid (GABA) and its associated chloride-ion channel. Benzodiazepine antagonists appear to block the potentiation by alcohol of GABA-induced chloride flux. Like the GABA-chloride channel, the *N*-methyl-D-aspartate (NMDA) receptors, which transduce signals carried by glutamate (the major excitatory transmitter in brain), are sensitive to extremely low concentrations of alcohol. There is also evidence that alcohol selectively potentiates serotonin 5-HT₃ receptor-ion currents, and the activity of this receptor has been implicated in alcohol- and drug-seeking behavior and addiction.

The effect of chronic administration of alcohol is to increase the number of neuronal calcium channels in the cell membrane; moreover, calcium channel blockers, given during chronic administration, prevent both the increase in neuronal calcium channels and the development of tolerance to alcohol ([Dolin and Little](#)). The significance of these findings has been demonstrated by Little and colleagues, who showed that calcium channel blockers, given to chronically intoxicated animals after withdrawal, prevent withdrawal convulsions.

The molecular mechanisms involved in the genesis of alcohol intoxication and tolerance are obviously far more complex than the foregoing remarks would indicate (see reviews by [Charness](#) and by [Samson and Harris](#)). There is now a vast literature on this subject, much of it contradictory. A unified concept of the role of neurotransmitters and their receptors and modulators in the production of alcohol intoxication and tolerance has yet to emerge. The role of internal cellular messengers, which have attracted much attention in the field of addiction, is also currently under investigation.

Physiologic Effects Alcohol functions not as a central nervous system (CNS) stimulant but as a depressant. Some of the early toxic effects of alcohol, such as garrulousness, aggressiveness, excessive activity, and increased electrical excitability of the cerebral cortex—all of them suggestive of cerebral stimulation—are thought to be due to the inhibition of certain subcortical structures (possibly the high brainstem reticular formation) that ordinarily modulate cerebrocortical activity. Similarly, the initial hyperactivity of tendon reflexes may represent a transitory escape of spinal motor neurons from higher inhibitory centers. With increasing amounts of alcohol, however, the depressant action spreads to involve the cortex as well as other brainstem and spinal neurons.

All manner of motor functions—whether the simple maintenance of a standing posture, the control of speech and eye movements, or highly organized and complex motor skills—are adversely affected by alcohol. The movements involved in these acts are not only slower than normal but also more inaccurate and random in character and therefore less well adapted to the accomplishment of specific ends.

Alcohol also impairs the efficiency of mental function by interfering with the speed of perception and the ability to persist in mental processing. The learning process is slowed and rendered less effective. Facility in forming associations, whether of words or of figures, and the ability to focus, sustain attention, and concentrate are reduced. The subject is less versatile in directing thought along new lines appropriate to the problem at hand. Finally, alcohol impairs the faculties of judgment and discrimination and, all in all, the ability to think and reason clearly.

A scale relating various degrees of functional impairment to blood alcohol levels in *nonhabituated* persons was constructed many years ago by Miles. At a blood alcohol level of 30 mg/dL, a mild euphoria was detectable, and at 50 mg/dL, a mild incoordination. At 100 mg/dL, ataxia was obvious; at 200 mg/dL, there was confusion and a reduced level of mental activity; at 300 mg/dL, the subjects were stuporous; and a level of 400 mg/dL—accompanied by deep anesthesia—was potentially fatal. These figures are valid provided that the alcohol content in the blood rises steadily over a 2-h period.

Tolerance It should be emphasized that a scale such as the one described above has virtually no value in the chronic alcoholic patient, for it does not take into account the adaptation of the organism to alcohol, i.e., the phenomenon of tolerance. It is common knowledge that a habituated person can drink more and show fewer effects than the moderate drinker or abstainer. This phenomenon accounts for the surprisingly large amounts of alcohol that the chronic drinker can consume without showing significant signs of drunkenness. Sober-appearing alcoholics may have blood alcohol levels of 400 to 500 mg/dL. The aspect of tolerance must always be considered in judging the significance of a single estimation of the blood alcohol concentration as an index of functional capacity.

The nervous system is capable of adapting to alcohol after a very short exposure. Thus, if the alcohol concentration in the blood is raised very slowly, few symptoms appear, even at quite high levels. Contrariwise, the degree of intoxication is more severe when the blood alcohol level peaks rapidly. As mentioned earlier, the important factor in this rapid adaptability is not so much the height of the blood alcohol concentration as the length of time the alcohol has been present in the body. If the dosage of alcohol that causes blood levels to be high is held constant, the blood alcohol concentration falls gradually and clinical evidence of intoxication disappears. The cause of this fall in alcohol concentration is not clear.

The mechanisms that underlie tolerance and addiction are just beginning to be understood. There is little evidence that an enhanced rate of alcohol metabolism can adequately account for the degree of tolerance observed in alcoholics. An increased degree of neuronal adaptation to alcohol is a more likely explanation. As mentioned earlier, the main factors that are operative in this adaptation are the increasing resistance of neuronal membranes to the “fluidizing” effects of alcohol and

an increase in the number of neuronal calcium channels in the cell membrane.

CLINICAL EFFECTS OF ALCOHOL ON THE NERVOUS SYSTEM

A large number of neurologic disorders are associated with alcoholism. The factor common to all of them, of course, is the abuse of alcohol, but the mechanism by which alcohol produces its effects varies widely from one group of disorders to another. The classification that follows is based for the most part on known mechanisms.

- I. Alcohol intoxication—drunkenness, coma, excitement (“pathologic intoxication”), “blackouts”
- II. The abstinence or withdrawal syndrome—tremulousness, hallucinosis, seizures, delirium tremens
- III. Nutritional diseases of the nervous system secondary to alcoholism
 - A. Wernicke-Korsakoff syndrome
 - B. Polyneuropathy
 - C. Optic neuropathy (“tobacco-alcohol amblyopia”)
 - D. Pellagra
- IV. Diseases of uncertain pathogenesis associated with alcoholism
 - A. Cerebellar degeneration
 - B. Marchiafava-Bignami disease
 - C. Central pontine myelinolysis
 - D. “Alcoholic” myopathy and cardiomyopathy
 - E. Alcoholic dementia
 - F. Cerebral atrophy
- V. Fetal alcohol syndrome
- VI. Neurologic disorders consequent upon cirrhosis and portal-systemic shunts
 - A. Hepatic stupor and coma
 - B. Chronic hepatocerebral degeneration

Alcohol Intoxication

The usual manifestations of alcohol intoxication are so commonplace that they require little elaboration. They consist of varying degrees of exhilaration and excitement, loss of restraint, irregularity of behavior, loquacity and slurred speech, incoordination of movement and gait, irritability, drowsiness, and, in advanced cases, stupor and coma. There are several *complicated* types of alcohol intoxication, which are considered below.

Pathologic Intoxication Despite what has been said above, on rare occasions, alcohol has an excitatory rather than a sedative effect. This reaction has been referred to in the past as *pathologic*, or *complicated*, *intoxication* and as *acute alcoholic paranoid state*. Since all forms of intoxication are pathologic, *atypical intoxication* or *idiosyncratic alcohol intoxication* are more appropriate designations. Nevertheless, the term *pathologic intoxication* is still widely used. The boundaries of this syndrome have never been clearly drawn. In the past, variant forms of delirium tremens and epileptic phenomena as well as psychopathic and criminal behavior were indiscriminately included. Now the term is generally used to designate an outburst of blind fury with assaultive and destructive behavior. Often the patient is subdued only with difficulty. The attack terminates with deep sleep, which occurs spontaneously or in response to parenteral sedation; on awakening, the patient has no memory of the episode. Lesser degrees are also known wherein the patient, after several drinks, repeatedly commits gross social indiscretions. Allegedly this reaction may follow the ingestion of a small amount of alcohol, but in our experience the amount has always been substantial. Unlike the usual forms of alcohol intoxication and withdrawal, the atypical form has not been produced in experimental subjects, and the diagnosis depends upon the aforementioned arbitrary anecdotal criteria.

Pathologic intoxication has been ascribed to many factors, the common ones being constitutional differences in the susceptibility to alcohol (idiosyncratic reaction to alcohol), pre-existent craniocerebral trauma or other brain disease, and an underlying “hysterical or epileptoid temperament or sociopathy.” There are no meaningful data to support any of these beliefs. However, an analogy may be drawn between pathologic intoxication and the paradoxical reaction that occasionally follows the administration of barbiturates or other sedative drugs.

The diagnosis of pathologic or idiosyncratic intoxication could conceivably have important legal implications. Because of long-held public and legal attitudes, a person suffering from alcoholism or the *usual* forms of drunkenness is considered to be responsible for the consequences of his drinking, whereas a person with pathologic intoxication might be considered insane at the time and therefore not responsible. The main disorders to be distinguished from pathologic intoxication are temporal lobe seizures that occasionally take the form of outbursts of rage and violence and the explosive episodes of violence that characterize the behavior of certain sociopaths. The diagnosis in these cases may be difficult and depends on eliciting the other manifestations of temporal lobe epilepsy or sociopathy.

Alcoholic “Blackouts” In the language of the alcoholic, the term *blackout* refers to an interval of time, during a period of severe intoxication, for which the patient, when sober, has no memory—even though the state of consciousness, as observed by others, was not grossly altered during that interval. However, a systematic assessment of mental function during the amnesic period has usually not been made. A few observations indicate that it is short-term (retentive) memory, rather than immediate or long-term memory, that is impaired; this feature and the subsequent amnesia for the episode are somewhat reminiscent of the disorder known as *transient global amnesia* (page 457).

The nature and significance of such episodes are unclear. It is widely held that the occurrence of blackouts is an early and serious indicator of the development of alcohol addiction. In our experience, blackouts may occur at any time in the course of alcoholism, even during the first drinking experience, and they certainly have happened in persons who never became alcoholics. The salient facts are that there is a degree of intoxication which interferes with the registration of events and the formation of memories during the period of intoxication, and that the amount of alcohol consumed in moderate social drinking will rarely produce this effect.

Alcoholic Stupor and Coma As has been indicated, the symptoms of alcoholic intoxication are the result of the depressant action of alcohol on cerebral and spinal neurons. In this respect alcohol acts on nerve cells in a manner akin to the general anesthetics. Unlike the latter, however, the margin between the dose of alcohol that produces surgical anesthesia and that which dangerously depresses respiration is a narrow one, a fact that adds an element of urgency to the diagnosis and treatment of alcoholic narcosis. One must also be alert to the possibility that barbiturates or other sedative-hypnotic drugs may have potentiated the depressant effects of alcohol.

The signs of alcohol intoxication are distinctive and most forms present no problem in diagnosis or management. On the other hand, coma due to alcohol may present difficulties in differential diagnosis. It should be stressed that the diagnosis of alcoholic coma is made not merely on the basis of a flushed face, stupor, and the odor of alcohol but only after the careful exclusion of all other causes of coma (page 383).

Treatment of Alcohol Intoxication Mild to moderate degrees of intoxication require no special treatment. Certain time-honored forms of stimulation—such as a cold shower, strong coffee, forced activity, or induction of vomiting—may be helpful, but there is no evidence that any of them influences the rate of disappearance of alcohol from the blood. Alcoholic stupor is also a relatively brief, self-limited state; if the vital signs are normal, no special therapeutic measures are necessary. *Pathologic intoxication* may require the use of restraints and the parenteral administration of diazepam (5 to 10 mg) or haloperidol (2 to 5 mg), repeated once after 30 to 40 min if necessary.

Coma due to alcohol intoxication represents a medical emergency. The main object of treatment is to prevent respiratory depression and the complications it engenders. The management of the comatose patient is described in [Chap. 17](#). One would like to lower the blood alcohol level as rapidly as possible, but the administration of fructose or of insulin and glucose for this purpose is of little practical value. Analeptic drugs such as amphetamine and various mixtures of caffeine and picrotoxin are antagonistic to alcohol only insofar as they are powerful cerebrocortical stimulants and overall nervous system excitants; they do not hasten the oxidation of alcohol. The use of hemodialysis should be considered in comatose patients with extremely high blood alcohol concentrations (>500 mg/dL), particularly if accompanied by acidosis, and in those who have concurrently ingested methanol or ethylene glycol or some other dialyzable drug.

Methyl, Amyl, and Isopropyl Alcohols and Ethylene Glycol Poisoning with alcohols other than ethyl alcohol is a relatively rare occurrence. *Amyl alcohol* (fusel oil) and *isopropyl alcohol* are used as industrial solvents and in the manufacture of varnishes, lacquers, and pharmaceuticals; in addition, isopropyl alcohol is readily

available as a rubbing alcohol. Intoxication may follow the ingestion of these alcohols or inhalation of their vapors. The effects of both are much like those of ethyl alcohol, but much more toxic.

Methyl alcohol (methanol, wood alcohol) is a component of antifreeze and many combustibles and is used in the manufacture of formaldehyde, as an industrial solvent, and as an adulterant of alcoholic beverages, the latter being the most common source of methyl alcohol intoxication. The oxidation of methyl alcohol to formaldehyde and formic acid proceeds relatively slowly; thus, signs of intoxication do not appear for several hours or may be delayed for a day or longer. Many of the toxic effects are like those of ethyl alcohol, but in addition severe methyl alcohol poisoning may produce serious degrees of acidosis (with an anion gap), damage to retinal ganglion cells—giving rise to scotomata and varying degrees of blindness, dilated unreactive pupils, and retinal edema—and bilateral degeneration of the putamens, readily visible on computed tomography (CT) scans. Survivors may be left blind and parkinsonian ([McLean](#) et al). The most important aspect of treatment is the intravenous administration of large amounts of sodium bicarbonate. Hemodialysis may be a useful adjunct because of the slow rate of oxidation of methanol.

Ethylene glycol, an aliphatic alcohol, is a commonly used industrial solvent and the major constituent of antifreeze. In the latter form it is sometimes consumed by skid-row alcoholics (5000 cases of poisoning annually in the United States), with disastrous results. At first the patient merely appears drunk, but after a period of 4 to 12 h, hyperventilation and severe metabolic acidosis develop, followed by confusion, convulsions, coma, and renal failure in rapid succession. Cerebrospinal fluid lymphocytosis is a characteristic feature. The metabolic acidosis is due to the conversion of ethylene glycol by alcohol dehydrogenase into glycolic acid, thus producing an anion gap that reflects the presence of this substance in the blood. The cause of the renal toxicity is less clear—probably it is due to the formation of oxalate from glycolate and the deposition of oxalate crystals. These appear in the urine and sometimes in the CSF and aid in diagnosis. The treatment of ethylene glycol poisoning has, until relatively recently, consisted of hemodialysis and the intravenous infusion of sodium bicarbonate and ethanol, the latter serving as a competitive substrate for alcohol dehydrogenase. However, the use of ethanol in this regimen is problematic. Baud and colleagues and more recently Brent et al and Jacobsen have advocated the use of intravenous 4-methylpyrazole (fomepizole), which is a far more effective inhibitor of alcohol dehydrogenase than is alcohol. They recommend this form of treatment for methanol poisoning as well.

Some of the patients who recover from the acute renal and metabolic effects are left with multiple cranial nerve defects, particularly of the seventh and eighth nerves. The latter abnormalities develop 6 to 18 days after the ingestion of ethylene glycol and have been attributed to the deposition of oxalate crystals along the subarachnoid portions of the affected nerves ([Spillane](#) et al).

The Abstinence, or Withdrawal, Syndrome

Included under this title is the symptom complex of tremulousness, hallucinations, seizures, confusion, and psychomotor and autonomic overactivity. Although a sustained period of chronic inebriation is the most obvious factor in the causation of these symptoms, they become manifest only after a *period of relative or absolute abstinence* from alcohol—hence the designation *abstinence*, or *withdrawal*, syndrome. This concept is illustrated in [Fig. 42-1](#). Each of the major manifestations of the withdrawal syndrome may occur in more or less pure form and are so described below, but usually they occur in various combinations. Major withdrawal symptoms are observed mainly in the spree, or periodic, drinker, although the steady drinker is not immune if for some reason he stops drinking. The full syndrome, depicted further on, is called *delirium tremens*.

Figure 42-1Relation of acute neurologic disturbances to cessation of drinking. The shaded drinking period is greatly foreshortened and not intended to be quantitative. The periodic notching in the baseline represents the tremulousness, nausea, and so on that occur following a night's sleep. The time relations of the various groups of symptoms to withdrawal are explained in the text. (Adapted from Victor M, Adams RD: *The effect of alcohol on the nervous system*. Res Publ Assoc Res Nerv Ment Dis 32:526, 1953, by permission.)

Tremulousness and Associated Symptoms The most common single manifestation of the abstinence syndrome is tremulousness, often referred to as “the shakes” or “the jitters,” combined with general irritability and gastrointestinal symptoms, particularly nausea and vomiting. These symptoms first appear after several days of drinking, usually in the morning after a night's abstinence. The patient “quiets his nerves” with a few drinks and is then able to drink for the rest of the day without undue distress. The symptoms return on successive mornings with increasing severity. The duration of drinking of this type varies greatly. It is terminated most often because of increasing severity of the recurrent tremor and vomiting, but for other reasons as well, such as profound general weakness, self-disgust, injury, concurrent illness, a lack of funds, and so forth. The symptoms then become greatly augmented, reaching their peak intensity 24 to 36 h after the complete cessation of drinking.

At this stage, the patient presents a distinctive clinical picture. The face is deeply flushed, the conjunctivae are injected, and there is usually tachycardia, anorexia, nausea, and retching. The patient is fully awake, startles easily, and complains of insomnia. He is inattentive, and disinclined to answer questions, and may respond in a rude or perfunctory manner. The patient may be mildly disoriented in time and have a poor memory for events of the last few days of the drinking spree, but he shows no serious confusion, being generally aware of his immediate surroundings and the nature of his illness.

Generalized tremor is the most obvious feature of this illness. It is of fast frequency (6 to 8 Hz), slightly irregular, and variable in severity, tending to diminish when the patient is in quiet surroundings and to increase with motor activity or emotional stress. The tremor may be so violent that the patient cannot stand without help, speak clearly, or eat without assistance. Sometimes there is little objective evidence of tremor, and the patient complains only of being “shaky inside.”

Within a few days, the flushed facies, anorexia, tachycardia, and tremor subside to a large extent, but the overall alertness, tendency to startle easily, and jerkiness of movement may persist for a week or longer, and the feeling of uneasiness may not leave the patient completely for 10 to 14 days. These features are suggestive of adrenergic hyperactivity, and indeed the concentrations of norepinephrine and its metabolites are elevated in both the blood and CSF ([Hawley](#) et al). According to Porjesz and Begleiter, certain electrophysiologic abnormalities (diminished amplitudes of sensory evoked potentials and prolonged latencies and conduction velocities of auditory brainstem potentials) remain altered long after the clinical abnormalities have subsided.

Hallucinosis Symptoms of disordered perception occur in about one-quarter of hospitalized tremulous patients. The patient may complain of “bad dreams”—nightmarish episodes associated with disturbed sleep—which he finds difficult to separate from real experience. Sounds and shadows may be misinterpreted, or familiar objects may be distorted and assume unreal forms (illusions). Although these are not hallucinations in the strict sense of the term, they represent the most common forms of disordered sense perception in the alcoholic.

Hallucinations may be purely visual in type, mixed visual and auditory, tactile, or olfactory, in this order of frequency. There is little evidence to support the popular belief that certain visual hallucinations (bugs, pink elephants) are specific to alcoholism. Actually, the hallucinations comprise the full range of visual experience. They are more often animate than inanimate; persons or animals may appear singly or in panoramas, shrunk or enlarged, natural and pleasant, or distorted, hideous, and frightening. The hallucinosis may be an isolated phenomenon lasting for a few hours and it may later be attended by other withdrawal signs.

Acute and Chronic Auditory Hallucinosis A special type of alcoholic psychosis, consisting of a more or less pure auditory hallucinosis, has been recognized for many years. Kraepelin referred to it as the “hallucinatory insanity of drunkards,” or “alcoholic mania.” A report of 75 such cases was made by Victor and Hope. The central feature of the illness, in the beginning, is the occurrence of auditory hallucinations despite an otherwise clear sensorium; i.e., the patients are not disoriented or obtunded, and they have an intact memory. The hallucinations may take the form of unstructured sounds such as buzzing, ringing, gunshots, or clicking (the

elementary hallucinations of Bleuler), or they may have a musical quality, like a low-pitched hum or chant. The most common hallucinations, however, are human voices. When the voices can be identified, they are often attributed to the patient's family, friends, or neighbors—rarely to God, radio, or radar. The voices may be addressed directly to the patient, but more frequently they discuss him in the third person. In the majority of cases the voices are maligning, reproachful, or threatening in nature and are disturbing to the patient; a significant proportion, however, are not unpleasant and leave the patient undisturbed. To the patient, the voices are clearly audible and intensely real, and they tend to be exteriorized; i.e., they come from behind a radiator or door, from the corridor, or through a wall, window, or floor. Another feature of auditory hallucinosis (and of visual hallucinosis as well) is that the patient's response is more or less understandable in light of the hallucinatory content. The patient may call on the police for protection or erect a barricade against invaders; he may even attempt suicide to avoid what the voices threaten. The hallucinations are most prominent during the night, and their duration varies greatly: they may be momentary, or they may recur intermittently for days on end and, in exceptional instances, for weeks or months.

While hallucinating, most patients have no appreciation of the unreality of their hallucinations. With improvement, the patient begins to question the reality of his hallucinations and may be reluctant to talk about them and may even question his own sanity. Full recovery is characterized by the realization that the voices were imaginary and by the ability to recall, sometimes with remarkable clarity, some of the abnormal thought content of the psychotic episode.

A unique feature of this alcoholic psychosis is its evolution, in a small proportion of the patients, to a state of *chronic auditory hallucinosis*. The chronic disorder begins like the acute one, but after a short period, perhaps a week or two, the symptomatology begins to change. The patient becomes quiet and resigned, even though the hallucinations remain threatening and derogatory. Ideas of reference and influence and other poorly systematized paranoid delusions become prominent. At this stage the illness may be mistaken for paranoid schizophrenia and indeed was so identified by Bleuler. There are, however, important differences between the two disorders: the alcoholic illness develops in close relation to a drinking bout and the past history rarely reveals schizoid personality traits. Moreover, alcoholic patients with hallucinosis are not distinguished by a high incidence of schizophrenia within their families ([Schuckit and Winokur](#), Scott), and a large number of such patients, whom we evaluated long after their acute attacks, did not show an increased incidence of schizophrenia. There is some evidence that repeated attacks of acute auditory hallucinosis render the patient more susceptible to the chronic state.

Withdrawal Seizures (“Rum Fits”) In the setting of alcohol withdrawal (i.e., where relative or absolute abstinence follows a period of chronic inebriation), convulsive seizures are a common occurrence. More than 90 percent of withdrawal seizures occur during the 7- to 48-h period following the cessation of drinking, with a peak incidence between 13 and 24 h. During the period of seizure activity, the electroencephalogram (EEG) is usually abnormal, but it reverts to normal in a matter of days, even though the patient may go on to develop delirium tremens. Also during the period of seizure activity, the patient is unusually sensitive to stroboscopic stimulation; almost half the patients respond with generalized myoclonus or a convulsive seizure (photomyogenic or photoparoxysmal response). By contrast, this type of response to photic stimulation is observed only rarely in nonalcoholic epileptics, and then usually in those with tonic-clonic seizures on awakening.

Seizures occurring in the abstinence period have a number of other distinctive features. There may be only a single seizure, but in the majority of cases the seizures occur in bursts of two to six, occasionally even more; 2 percent of our patients developed status epilepticus. The seizures are grand mal in type, i.e., generalized, tonic-clonic convulsions with loss of consciousness. Focal seizures should always suggest the presence of a focal lesion (most often traumatic) in addition to the effects of alcohol. Twenty-eight percent of our patients with generalized withdrawal seizures went on to develop delirium tremens (the percentage has been less in other series); invariably the seizures preceded the delirium. The postictal confusional state may blend imperceptibly with the onset of the delirium, or the postictal state may clear over several hours or even a day or longer before the delirium sets in. Seizures of this type typically occur in patients whose drinking history has extended over a period of many years and must be distinguished from other forms of seizures that have their onset in adult life.

It is suggested that the term *rum fits*, or *whiskey fits*—i.e., the names sometimes used by alcoholics—be reserved for seizures with the attributes described above. This serves to distinguish the form of seizure activity that occurs only in the immediate abstinence period from seizures that occur in the interdrinking period, long after withdrawal has been accomplished.

It is important to note that the common idiopathic or posttraumatic forms of epilepsy are also influenced by alcohol. In these types of epilepsy, a seizure or seizures may be precipitated by only a short period of drinking (e.g., a weekend, or even one evening of heavy social drinking); interestingly, in these circumstances, the seizures occur not when the patient is intoxicated but usually the morning after, in the “sobering-up” period.

The EEG findings in alcoholic subjects with abstinence seizures do not support the notion that the seizures merely represent latent epilepsy made manifest by alcohol. Instead, the EEG reflects a sequence of changes induced by alcohol itself: a decrease in the frequency of brain waves during the period of chronic intoxication; a rapid return of the EEG toward normal immediately after cessation of drinking; a brief period of dysrhythmia (sharp waves and paroxysmal discharges) that coincides with the flurry of convulsive activity; and again, a rapid return of the EEG to normal. Except for the transient dysrhythmia in the withdrawal period, the incidence of EEG abnormalities in patients who have had rum fits is no greater than in normal persons, in sharp contrast to the EEGs of nonalcoholic patients with recurrent seizures.

Treatment of Withdrawal Seizures Many cases do not require the use of anticonvulsant drugs, since the entire episode of seizure activity—whether a single seizure or a brief flurry of seizures—may have terminated before the patient is brought to medical attention. The parenteral administration of diazepam or sodium phenobarbital early in the withdrawal period could conceivably prevent rum fits in patients with a previous history of this disorder or those who might be expected to develop seizures on withdrawal of alcohol, but this prophylactic plan has never been documented satisfactorily. Recently however, D'Onofrio and colleagues have presented data that support the effectiveness of intravenous lorazepam (2 mg in 2 mL of normal saline) in preventing *recurrent seizures* in the withdrawal period. The long-term administration of anticonvulsants is not practical: if such patients remain abstinent, they will be free of seizures; if they resume drinking, they usually abandon their medicines. Furthermore, it is not certain that continued administration of anticonvulsants dependably prevents abstinence seizures. The rare instances of status epilepticus should be managed like status of any other type (page 361). In alcoholics with a history of idiopathic or posttraumatic epilepsy, the goal of treatment should be abstinence from alcohol, because of the tendency of even short periods of drinking to precipitate seizures. Such patients need to be maintained on anticonvulsant drugs.

Delirium Tremens (“DTs”) This is the most dramatic and grave of all the alcoholic illnesses. It is characterized by profound confusion, delusions, vivid hallucinations, tremor, agitation, and sleeplessness as well as by the signs of increased autonomic nervous system overactivity—i.e., dilated pupils, fever, tachycardia, and profuse perspiration. The clinical features of delirium are presented in detail in [Chap. 20](#).

Delirium tremens develops in one of several settings. The patient, an excessive and steady drinker for many years, may have been admitted to the hospital for an unrelated illness, accident, or operation and, after 2 to 4 days, occasionally even later, becomes delirious. Or, following a prolonged drinking binge, the patient may have experienced several days of tremulousness and hallucinosis or one or more seizures and may even be recovering from these symptoms when delirium tremens develops, rather abruptly as a rule.

As to the frequency of delirium tremens, Foy and Kay reported an incidence of 0.65 percent of all patients admitted for other reasons to a large general hospital. Among 200 consecutive alcoholics admitted to a city hospital, Ferguson et al reported that 24 percent developed delirium tremens; of these, 8 percent died—figures that are considerably higher than those recorded in our hospitals. Of course, the reported incidence of delirium tremens will vary greatly, depending on the population served by a particular hospital, the admission policy of the hospital, and the strictness with which delirium tremens is defined and distinguished from lesser forms of alcohol withdrawal.

In the majority of cases delirium tremens is benign and short-lived, ending as abruptly as it begins. Consumed by relentless activity and wakefulness for several days, the patient falls into a deep sleep and then awakens lucid, quiet, and exhausted, with virtually no memory of the events of the delirious period. Somewhat less commonly, the delirious state subsides gradually with intermittent episodes of recurrence. In either event, when delirium tremens occurs as a single episode, the duration is 72 h or less in over 80 percent of cases. Less frequently still, there may be one or more relapses, several episodes of delirium of varying severity being separated by intervals of relative lucidity—the entire process lasting for several days or occasionally for as long as 4 to 5 weeks.

In the past, approximately 15 percent of cases of delirium tremens ended fatally, but the figure now is closer to 5 percent. In many of the fatal cases there is an associated infectious illness or injury, but in others no complicating illness is discernible. Many of the patients die in a state of hyperthermia; in some, death comes so suddenly that the nature of the terminal events cannot be determined. Reports of a negligible mortality in delirium tremens can usually be traced to a failure to distinguish between delirium tremens and the minor forms of the withdrawal syndrome, which are far more common and practically never fatal.

Atypical Delirious-Hallucinatory or Confusional States These are alcohol withdrawal states, closely related to delirium tremens and about as frequent, in which

one facet of the delirium tremens complex assumes prominence, to the virtual exclusion of the other symptoms. The patient may simply exhibit a transient state of quiet confusion, agitation, or peculiar behavior lasting several days or weeks. Or there may be a vivid hallucinatory-delusional state and abnormal behavior consistent with the patient's false beliefs. Unlike typical delirium tremens, the atypical states usually present as a single circumscribed episode without recurrences, are only rarely preceded by seizures, and do not end fatally. This may be another way of saying that they are a partial or less severe form of the disease.

Pathology *Pathologic examination* is singularly unrevealing in patients with delirium tremens. Edema and brain swelling have been absent in the authors' pathologic material except when shock or hypoxia had occurred terminally. There have been no significant light-microscopic changes in the brain, which is what one would expect in a disease that is essentially reversible. Abnormalities of the CSF occur unpredictably, as do changes on CT scanning or MRI; they may indicate the presence of some medical or surgical complication. Enlargement of the third and lateral ventricles is a common finding (see below). The EEG findings have been discussed in relation to withdrawal seizures.

Other Laboratory Findings Rarely, blood glucose is seriously depressed in the alcohol withdrawal states, for the reasons given earlier, under “Absorption, Distribution, and Metabolism of Alcohol.” Ketoacidosis with normal blood glucose is another infrequent finding. Disturbances of electrolytes are of varying frequency and significance. Serum sodium levels are altered infrequently and are more often increased than decreased. The same is true for chlorides and phosphate. Serum calcium and potassium were found to be lowered in about one-quarter of our patients. Most patients show some degree of hypomagnesemia, low P CO₂, and high arterial pH—abnormalities that are probably important in the pathogenesis of withdrawal symptoms (see below).

Pathogenesis of the Tremulous-Hallucinatory-Delirious Disorders For many years prior to 1950, it was the common belief that these symptoms represented the most severe forms of alcohol intoxication—an idea that fails to satisfy the simplest clinical logic. The symptoms of toxicity—consisting of slurred speech, uninhibited behavior, staggering gait, stupor, and coma—are in themselves distinctive and, in a sense, the opposite of the symptom complex of tremor, fits, and delirium. The former symptoms are associated with an elevated blood alcohol level, whereas the latter become evident only when the blood alcohol has been reduced. Finally, the symptoms of intoxication increase in severity as more alcohol is consumed, whereas tremor and hallucinosis and even full-blown delirium tremens are diminished or nullified by the administration of alcohol. Also, although much discussed in the past, there is no convincing evidence that an endocrine abnormality (other than the central release of norepinephrine) or nutritional deficiency plays a role in the genesis of delirium tremens and related symptoms.

It is evident, from observations in both humans and experimental animals, that the most important and the one indispensable factor in the genesis of delirium tremens and related disorders is the withdrawal of alcohol following a period of sustained chronic intoxication. Further, the emergence of withdrawal symptoms depends upon a *decline* in the blood alcohol level from a previously higher level and not necessarily upon the complete disappearance of alcohol from the blood.

The mechanisms by which the withdrawal of alcohol produces symptoms are only beginning to be understood. In all but the mildest cases, the early phase of alcohol withdrawal (beginning within 7 to 8 h after cessation of drinking) is attended by a drop in serum magnesium concentration and a rise in arterial pH—the latter on the basis of respiratory alkalosis ([Wolfe and Victor](#)). Possibly the compounded effect of these two factors, both of which are associated with hyperexcitability of the nervous system, is responsible for seizures and for other symptoms that characterize the early phase of withdrawal. As an explanation of delirium tremens, however, hypomagnesemia is probably not important, since the serum magnesium level has frequently been restored to normal before the onset of the delirium. The respiratory alkalosis can be explained by the fact that, with chronic alcohol intoxication, certain aggregates of respiratory-related neurons in the lateral medullary tegmentum are rendered progressively more insensitive to circulating CO₂; in the “rebound” phase, these cells become more sensitive than normal to CO₂, with resultant hyperventilation and a rise in arterial pH. The molecular mechanisms that are thought to be operative in the genesis of alcohol tolerance and withdrawal have been considered above. The GABAergic system has been most strongly implicated, in part because the receptors for this inhibitory transmitter are downregulated by chronic alcohol use, but the situation is not nearly so simple, insofar as the excitatory glutaminergic system is also inhibited by alcohol.

Treatment of Delirium Tremens and Minor Withdrawal Symptoms The general aspects of management of the delirious and confused patient have been described on page 442. More specifically, the treatment of delirium tremens begins with a careful search for associated injuries (particularly head injury with cerebral lacerations or subdural hematoma), infections (pneumonia or meningitis), pancreatitis, and liver disease. Because of the frequency and seriousness of these complications, chest films and a CT scan should be obtained in most instances, and lumbar puncture should be performed if there is the slightest suspicion of meningitis. In severe forms of delirium tremens, the temperature, pulse, and blood pressure should be noted at frequent intervals in anticipation of peripheral circulatory collapse and hyperthermia, which, added to the effects of injury and infection, are the usual causes of death in this disease. In the case of hypotension, one must act quickly, utilizing intravenous fluids and, if called for, vasopressor drugs. The occurrence of hyperthermia demands the use of a cooling mattress or evaporative cooling in addition to specific treatment for any infection that may be present.

An important element in treatment is the correction of fluid and electrolyte imbalance. Severe degrees of agitation and perspiration may require the administration of up to 5 L of fluid daily, of which at least 1500 to 2000 mL should be normal saline. The specific electrolytes and the amounts that must be administered are governed by the laboratory values for these electrolytes. If the serum sodium is extremely low, one must be cautious in raising the level lest a central pontine myelinolysis be induced (see page 1193). In the rare case of hypoglycemia, the administration of glucose is an urgent matter. Patients who present with severe ketoacidosis and normal or only slightly elevated blood glucose concentrations usually recover promptly, without the use of insulin.

It must be emphasized again that a *special danger attends the use of glucose solutions in alcoholic patients*. The administration of intravenous glucose may serve to consume the last available reserves of thiamine and precipitate Wernicke disease, as discussed in [Chap. 41](#). Typically, these patients have subsisted on a diet disproportionately high in carbohydrate (in addition to alcohol, which is metabolized entirely as carbohydrate) and low in thiamine, and their body stores of B vitamins may have been further reduced by gastroenteritis and diarrhea. For this reason it is good practice to add B vitamins, specifically thiamine (which may also be supplemented by intramuscular injection), in all cases requiring parenterally administered glucose—even though the alcoholic disorder under treatment, e.g., delirium tremens, is not primarily due to vitamin deficiency.

With respect to the use of medications, it is important to distinguish between mild withdrawal symptoms, which are essentially benign and responsive to practically any sedative drug, and delirium tremens, which has a serious mortality and is relatively unresponsive to drugs. In the case of minor withdrawal symptoms, the purpose of medication is to ensure rest and sleep. This can be carried out on a hospital ward or a special “detoxification” unit. However, there is no certain way to predict whether a patient with the early signs of withdrawal will progress to a state of delirium tremens. In the latter state, the object of drug therapy is to blunt the psychomotor overactivity and prevent exhaustion and facilitate the administration of parenteral fluid and nursing care; one should not attempt to suppress agitation at all costs, since doing so requires an amount of drug that might seriously depress respiration.

A wide variety of drugs are effective in controlling withdrawal symptoms. The more popular ones in recent years have been chlordiazepoxide (Librium), diazepam (Valium), meprobamate, hydroxyzine (Vistaril) and the ancillary medications, clonidine and beta-adrenergic blockers, and newer anticonvulsant drugs such as gabapentin, which may reduce the requirement for sedative drugs. There is little to choose among these drugs in respect to their therapeutic efficacy. More importantly, there are few data to indicate that any one of them can prevent hallucinosis or delirium tremens or shorten the duration or alter the mortality rate of the latter disorder ([Kaim](#) et al). In general, phenothiazine drugs should be avoided because they reduce the threshold to seizures.

Currently, chlordiazepoxide and diazepam are the most frequently used drugs for treatment of withdrawal symptoms. If parenteral medication is necessary, we prefer 10 mg of diazepam or chlordiazepoxide given intravenously and repeated once or twice at 20- to 30-min intervals until the patient is calm but awake. Virtually equivalent alternatives are sodium phenobarbital in doses of 120 mg or haloperidol (10 mg) repeated at 3- to 4-h intervals intramuscularly (provided there is no serious liver disease). Beta-blocking agents, such as propranolol and atenolol, are helpful in reducing heart rate, blood pressure, and the tremor to some extent. Lofexidine, an alpha₂ agonist that blocks autonomic outflow centrally, and clonidine are similarly effective. Corticosteroids have no place in the treatment of the withdrawal syndrome.

Nutritional Diseases of the Nervous System

Alcoholism provides the ideal setting for the development of nutritional diseases of the nervous system. Although only a small proportion of alcoholics develop nutritional diseases, the overall number of these diseases is substantial because of the frequency of alcoholism. The importance of the alcohol-induced deficiency diseases relates to the fact that they are preventable and, if neglected, may lead to permanent disability. These illnesses are discussed fully in the preceding chapter, “Diseases of the Nervous System Due to Nutritional Deficiency.”

Disorders of Uncertain Pathogenesis Associated with Alcoholism

Also discussed in [Chap. 41](#) are so-called *alcoholic cerebellar degeneration* and *Marchiafava-Bignami disease*. The former is almost certainly of nutritional origin; in the latter a nutritional-metabolic etiology seems likely but has not been established. Central pontine myelinolysis, though frequently observed in alcoholics, is more appropriately considered with the acquired metabolic disorders ([Chap. 40](#)). Certain disorders of skeletal and cardiac muscle associated with alcoholism (*alcoholic myopathy and cardiomyopathy*) are described in [Chap. 51](#), with the myopathies due to drugs and toxins. There remain to be discussed several diverse disorders that have been attributed to alcoholism but whose causal relationship to alcohol abuse, nutritional deficiency, or some other factor is not clear.

Alcoholic Dementia and Cerebral Atrophy The term *alcoholic dementia* is used widely and often indiscriminately to designate a presumably distinctive form of dementia that is attributable to the chronic, direct effects of alcohol on the brain. An immediate problem with this category of alcoholic disease is its definition. A syndrome subsumed under the title of *alcoholic dementia* and its many synonyms (*alcoholic deteriorated state*, *chronic alcoholic psychosis*, *chronic or organic brain syndrome due to alcohol*) has never been delineated satisfactorily, either clinically or pathologically. In the *Comprehensive Textbook of Psychiatry*, it has been defined as “a gradual disintegration of personality structure, with emotional lability, loss of control, and dementia” ([Sadock and Sadock](#)). To other psychiatrists ([Strecker](#) et al), the alcoholic deteriorated state denotes “the common end reaction of all chronic alcoholics who do not recover from their alcoholism or do not die of some accident or intercurrent episode.” Purported examples of this state show a remarkably diverse group of symptoms, including jealousy and suspiciousness; coarsening of moral fiber and other personality and behavioral disorders; deterioration of work performance, personal care, and living habits; and disorientation, impaired judgment, and defects of intellectual function, particularly of memory. Some early authors were apparently impressed with similarities between the alcoholic deteriorated state and general paresis, hence the term *alcoholic pseudoparesis*. Mercifully this term no longer appears in medical writings.

In recent years, there have been attempts to redefine alcoholic dementia. Cutting and also Lishman have expressed the view that the term *Korsakoff psychosis* should be limited to patients with a fairly pure disorder of memory of acute onset and that patients with more global symptoms of intellectual deterioration, of gradual evolution, be considered to have alcoholic dementia. These are rather weak diagnostic criteria. As pointed out in [Chap. 41](#), *Korsakoff psychosis* may have an insidious onset and gradual progression, and patients with this disorder, in addition to an amnesic defect, characteristically show disturbances of cognitive functions that depend little or not at all on memory. More importantly, in none of the patients designated by these authors as having alcoholic dementia was there a neuropathologic examination, without which the clinical assessment must remain arbitrary and imprecise.

The pathologic changes that purportedly underlie primary alcoholic dementia are even less precisely defined than the clinical syndrome. Courville, whose writings have been quoted most frequently in this respect, described a series of cerebral cortical changes that he attributed to the toxic effects of alcohol. Some of these changes turn out on close inspection to be quite nonspecific. Many of the cellular changes noted by Courville may have reflected a state of hepatic failure or terminal anoxia, and others reflect nothing more than the effects of aging or the insignificant artifacts of tissue fixation and staining.

More recently, Harper and colleagues have reported that the mean brain weight is decreased in alcoholics and the pericerebral space is increased—findings that do no more than confirm the brain shrinkage that is demonstrable by CT scans in many alcoholics and is reversible with sustained abstinence (see below). Also, using an automated cell-counting method, they reported a reduction in the number of neurons in the superior frontal cortex. Other investigators, using more accurate (stereologic) counting methods, have not duplicated these findings ([Hansen](#) et al; Jensen and Pakkenberg), nor have experimental studies in animals settled the problem.

In our experience, the majority of cases that come to autopsy with the label of *alcoholic dementia* or *deteriorated state* prove to have the lesions of the Wernicke-Korsakoff syndrome. Traumatic lesions of varying degrees of severity are commonly added. Other cases show the lesions of anoxic or hepatic encephalopathy, communicating hydrocephalus, Alzheimer disease, ischemic necrosis, or some other disease quite unrelated to alcoholism. Practically always, in our material, the clinical state can be accounted for by one or a combination of these disease processes, and there has been no need to invoke a hypothetical toxic effect of alcohol on the brain. This has also been the experience of Torvik and associates; with a few exceptions, such as coincidental Alzheimer disease, all their cases that had been diagnosed as having alcoholic dementia turned out, on neuropathologic examination, to have the chronic lesions of Wernicke-Korsakoff disease.

In brief, the most serious flaw in the concept of a primary alcoholic dementia is that it lacks a distinctive, well-defined pathology. Until such time as the morphologic basis is established, its status must remain ambiguous. A more detailed discussion of this subject and of so-called alcoholic cerebral atrophy (see below) can be found in the review by one of the present authors (M.V.), listed in the References.

Cerebral Atrophy in Chronic Alcoholism This disorder, like the “alcoholic deteriorated state,” does not constitute a well-defined entity. The concept of alcoholic cerebral atrophy was the product originally of pneumoencephalographic studies. Relatively young alcoholics, some with and some without symptoms of cerebral disease, were often found to have enlarged cerebral ventricles and widened sulci, mainly of the frontal lobes (see, for example, reports of [Brewer and Perrett](#) and of [Haug](#)). Similar findings have been reported in chronic alcoholics examined by CT scanning and MRI (see review by [Carlen](#) et al).

The clinical correlates of these radiologic findings are quite unclear. In some patients, so-called cerebral atrophy is associated with an overt complication of alcoholism—e.g., the Wernicke-Korsakoff syndrome (about one-quarter of our autopsied cases). In other patients, there is a history of recurrent seizures or evidence of liver disease, cerebral trauma, or some other event that might have resulted in ventricular enlargement. More often, however, the finding of large ventricles comes as a surprise, no symptoms or signs of neuropsychiatric disease having been noted in the course of the usual neurologic and mental status testing. In this connection, the findings of Wilkinson are of particular importance. He demonstrated that in clinically normal alcoholics, the radiologic measures of “brain atrophy” were age-related; once the age factor was removed, the CT findings in these subjects did not differ significantly from those in nonalcoholic controls.

The term *alcoholic cerebral atrophy* implies that chronic exposure of the brain to alcohol causes an irreversible loss of cerebral tissue. However, this idea is open to criticism, for dilated ventricles have in fact been reversible to a considerable extent when abstinence is maintained ([Carlen](#) et al, [Lishman](#), [Zipursky](#) et al, [Schroth](#) et al). Moreover, a similar ventricular enlargement, or brain shrinkage, also reversible, has been observed in patients with the Cushing syndrome, anorexia nervosa, and Lennox-Gastaut syndrome (treated with ACTH and corticosteroids). This reversibility would suggest that a shift of fluids had occurred in the brain (over many months), rather than loss of tissue. A rapid increase of the alcohol-inhibited antidiuretic hormone or a rise in protein synthesis after alcohol withdrawal are other possible explanations. Until this matter has been studied further, it would be preferable to refer to this condition as an asymptomatic ventricular enlargement and sulcal widening in alcoholics, rather than as cerebral atrophy.

Alcoholic Paranoia and Jealousy These are outmoded terms that were used in the past to designate what was thought to be a special type of paranoid reaction in chronic alcoholics, in which the patient, usually a male, developed ideas of infidelity on the part of his wife. The delusions of jealousy that might occur acutely in the course of alcoholic intoxication or withdrawal, or chronically as part of the “alcoholic deteriorated state,” were generally not included under this rubric. The notion that pathologic jealousy merits classification as a distinctive complication of alcoholism is not warranted, since the morbid jealousy that develops in alcoholics differs in no essential way from that in nonalcoholics. Nevertheless, among individuals with the syndrome of morbid jealousy, chronic alcoholism may be an important associated factor (11 of 66 cases reported by Langfeldt). Among the alcoholic patients, the delusions of jealousy may at first be evident only in relation to episodes of acute intoxication, but later they evolve, through a stage of constant suspicion and efforts to detect infidelity, into a fixed morbid reaction that persists during periods of sobriety as well.

Fetal Alcohol Syndrome

That parental alcoholism may have an adverse effect on the offspring has been a recurrent theme in medical lore. Probably the first documented occurrence of such a relationship was that of [Sullivan \(1899\)](#), who reported that the mortality among the children of drunken mothers was more than two times greater than that among children of nondrinking women of “similar stock.” This increased mortality was attributed by Sullivan and later by Haggard and Jellinek to postnatal influences such as poor nutrition and a chaotic home environment rather than to the intrauterine effects of alcohol. The idea that maternal alcoholism could damage the fetus was generally rejected and relegated to the category of superstitions about alcoholism or the claims of temperance ideologues.

In the late 1960s, the effects of alcohol abuse on the fetus were rediscovered, so to speak. Lemoine and associates in France and then Ulleland and Jones and Smith in the United States described a distinctive pattern of abnormalities in infants born of severely alcoholic mothers. The affected infants are small in length in comparison to weight, and most of them fall below the third percentile for head circumference. They are distinguished also by the presence of short palpebral fissures (shortened distance between inner and outer canthi) and epicanthal folds; maxillary hypoplasia, micrognathia, indistinct philtrum, and thin upper lip; and longitudinally oriented palmar creases, flexion deformities of the fingers, and a limited range of motion of other joints. Cardiac anomalies (usually spontaneously closing septal defects), anomalous external genitalia, and cleft lip and palate are much more frequent than in the general population. The newborn infants suck and sleep poorly,

and many of them are irritable, restless, hyperactive, and tremulous; these last symptoms resemble those of alcohol withdrawal except that they persist.

The first long-term study of children with what has come to be called *fetal alcohol syndrome* (FAS) was reported by Jones and coworkers. Among 23 infants born to alcoholic mothers, there was a neonatal mortality of 17 percent; among the infants who survived the neonatal period, almost half failed to achieve normal weight, length, and head circumference or remained backward mentally to a varying degree, even under optimal environmental conditions. Several large groups of FAS children have now been observed for 20 years or longer (see [Streissguth](#)). Distractibility, inattentiveness, hyperactivity, and impairment of fine motor coordination are prominent features in early childhood. Most such children are given the diagnosis of attention-deficit hyperactivity disorder. Slow growth of head circumference is a consistent finding throughout infancy and childhood. The physical stigmata of the syndrome become less distinctive after puberty, but practically all adolescents are left with some degree of mental retardation and behavioral abnormalities.

The pathologic changes that underlie the FAS have been studied in a small number of cases. Clarren and colleagues found extensive leptomeningeal neuroglial heterotopias and an obstructive hydrocephalus. Neuronal ectopias in the cerebral white matter and agenesis of the corpus callosum were also present. Peiffer and colleagues described a broader spectrum of malformations, including cerebellar heterotopias similar to those of the Dandy-Walker syndrome, schizencephaly, agenesis of the corpus callosum, and signs of arrhinencephaly.

Although the relationship of this syndrome to severe maternal alcoholism seems undoubted, the mechanism by which alcohol produces its effects is not fully understood. It is noteworthy that infants born to nonalcoholic mothers who had been subjected to severe dietary deprivation during pregnancy (during World War II) were small and often premature, but these infants did not show the pattern of malformations that characterizes FAS. Alcohol readily crosses the placenta in humans and animals; in the mouse, rat, chick, miniature swine, and beagle dog, alcohol has been shown to have both embryotoxic and teratogenic effects. Thus, the evidence to date favors a toxic effect of alcohol, although a possible toxic effect of acetaldehyde and smoking and a possible contributory role for nutritional deficiency have not been totally excluded. As to the specific mechanisms by which alcohol impairs the growth and development of the fetus, a compromised blood flow to the placenta and an ethanol-induced increase in prostaglandins have been suggested but are as yet unproved hypotheses ([Schenker](#) et al).

Unequivocal cases of FAS observed to date have occurred only in infants born to severely alcoholic mothers (many of them with delirium tremens and liver disease) who continued to drink heavily throughout pregnancy. Far less secure is a relationship to lesser degrees of alcohol intake. Data derived from the collaborative study sponsored by the National Institutes of Health indicate that about one-third of the offspring of women who are heavy drinkers have the FAS. Abel and Sokol have estimated that the worldwide incidence of the FAS is 1.9 per 1000 live births and have pronounced it to be the leading known cause of mental retardation in the western world. The degree of maternal alcoholism that is necessary to produce the syndrome and the critical stage in gestation during which it occurs are still vague. The various teratogenic effects described above are estimated to occur in the embryonic period, i.e., in the first 2 months of fetal life. Other nonteratogenic effects appear to be related to periods during gestation when the fetus is exposed to particularly high alcohol levels.

Diagnostic difficulties arise when only certain components of the syndrome occur in association with heavy maternal drinking, in the absence of the fully developed syndrome; these have been termed *fetal alcohol effects*, and their incidence is more difficult to determine. A comprehensive account of alcohol-related birth defects and the controversial issues surrounding this subject is contained in a special issue of *Alcohol Health and Research World*, published by the National Institutes of Health (Vol. 18, 1994).

Neurologic Complications of Alcoholic Cirrhosis and Portal-Systemic Shunts

This category of alcoholic disease is discussed in [Chap. 40](#), in connection with the acquired metabolic disorders of the nervous system.

Treatment of Alcohol Addiction

Following recovery from the acute medical and neurologic complications of alcoholism, the underlying problem of alcohol dependence remains. To treat only the medical complications and leave the management of the drinking problem to the patient alone is shortsighted. Almost always, drinking is resumed, with a predictable recurrence of medical illness. For this reason the physician must be prepared to deal with the addiction or at least to initiate treatment.

The problem of excessive drinking is formidable but not nearly as hopeless as it is generally made out to be (see review of [O'Connor and Schottenfeld](#)). A common misconception among physicians is that specialized training in psychiatry and an inordinately large amount of time are required to deal with the addictive drinker. Actually, a successful program of treatment can be initiated by any interested physician, using the standard techniques of history taking, establishing rapport with the patient, and setting up a schedule of frequent visits, though not necessarily for prolonged periods. Our position on this matter was reinforced by a controlled study of problem drinkers in whom treatment was equally successful whether carried out by general practitioners or by specialists ([Drummond](#) et al). Useful points at which to undertake treatment are during convalescence from a serious medical or neurologic complication of alcoholism or in relation to loss of employment, arrest, or threatened divorce. Such a crisis may help to convince the patient, more than any argument presented by family or physician, that the drinking problem has reached serious proportions.

The requisite for successful treatment is total abstinence from alcohol; for all practical purposes, this represents the only permanent solution. It is generally agreed that any attempts to curb the drinking habit will fail if the patient continues to drink. There are said to be alcohol addicts who have been able to reduce their intake of alcohol and eventually to drink in moderation, but they must represent only a small proportion of the addict population. Also, it is frequently stated that alcoholics must recognize that they are alcoholics—i.e., that their drinking is beyond their control—and must express willingness to be helped. Undoubtedly there is truth in both these statements, but they should not be interpreted to mean that alcoholic patients must gain this recognition and willingness entirely on their own initiative and that they will be helped only after they have done so. The physician can do a great deal to help such patients understand the nature of their problem and thus to motivate them to accept treatment. The help of family, employer, courts, and clergy should be enlisted in an attempt to convince these patients that abstinence is preferable to chronic inebriety. Alcoholic patients must be made fully aware of the medical and social consequences of continued drinking and must also be made to understand that because of some constitutional peculiarity (like that of the diabetic, who cannot handle sugar), they are incapable of drinking in moderation. These facts should be presented in much the same way as one would explain the essential features of any other disease; there is nothing to be gained from adopting a punitive or moralizing attitude. Yet patients should not be given the idea that they are in no way to blame for their illness; there appears to be an advantage in making them feel that they are responsible for doing something about their drinking.

The prevalent belief that an alcoholic will not stop drinking under duress also requires qualification. In fact, one of the few careful studies of this matter disclosed that relatively few patients would have sought help unless pressure had been exerted by family or employer; furthermore, those who came to the clinic under duress of this sort did just as well as those who came voluntarily.

A number of methods have proved valuable in the short- and long-term management of patients. The more important of these are admission to a detoxification or special hospital unit, rehabilitative therapy, aversion treatment, the use of disulfiram (Antabuse), and the participation in self-help organizations for recovery from alcoholism. Detoxification clinics and special hospital units for the treatment of alcoholism are now widely available. The physician should be fully aware of all the community resources available for the management of this problem and should be prepared to take advantage of them in appropriate cases. Most inpatient programs include individual and group counseling, didactics about the illness and recovery, and family intervention. Outpatient treatment (of individuals or groups) is widely available, either from specialized facilities or from specialized therapists in general mental health facilities; family counseling is usually offered as well and is often beneficial. Most professional alcoholism treatment in the United States includes an introduction to the methods and utilization of Alcoholics Anonymous (AA, see below).

Aversion treatment consists of the simultaneous administration of a drink of alcohol and injection of an emetic. The violent nausea and vomiting that ensue are intended to create in the patient a strong revulsion for alcohol. This form of treatment, as well as other types of conditioned-reflex treatment, have been employed with some success in special clinics. Most of the facilities that offer aversion treatment also incorporate the features of conventional rehabilitation therapy and support involvement with AA.

Disulfiram interferes with the metabolism of alcohol, so that a patient who takes both alcohol and disulfiram accumulates an inordinate amount of acetaldehyde in the tissues, resulting in nausea, vomiting, and hypotension, sometimes pronounced in degree. It is no longer considered necessary to demonstrate these effects to patients; it is sufficient to warn them of the severe reactions that may result if they drink while they have the drug in their bodies. Treatment with disulfiram is instituted only after the patient has been sober for several days, preferably longer. It should never be given to patients with cardiac or advanced liver disease. The drug is taken each morning or at another suitable time daily in a dosage of 250 mg, preferably under supervision. This form of treatment may be of value in the spree or periodic

drinker, in whom relapse from abstinence usually represents an impulsive rather than a carefully planned or premeditated act. The patient taking disulfiram, aware of the dangers of mixing liquor and the drug, is “protected” against the impulse to drink, and this protection may be renewed every 24 h by the simple expedient of taking a pill. The willingness with which the patient accepts this form of treatment also serves as a rough test of his willingness to stop drinking. Should the patient drink while taking disulfiram, the ensuing reaction is usually severe enough to require medical attention, and a protracted spree can thus be prevented. Disulfiram may cause a polyneuropathy if continued over a period of months or years, but this is a rare complication.

Several other drugs may be helpful in maintaining abstinence. The opioid antagonist naltrexone (50 mg/day) has been used for this purpose, with mixed results. In Europe, a modicum of success has been achieved with acamprosate (2000 mg daily), but this drug is not yet available in the United States.

Alcoholics Anonymous (AA), an informal fellowship of recovering alcoholics, has proved to be the single most effective force in the rehabilitation of alcoholic patients. The philosophy of this organization is embodied in its “12 steps,” a series of principles for sober living that guide the patient to recovery. These steps have been adopted by analogous fellowships for recovery from other addictive states, such as compulsive overeating, gambling, and dependence on narcotics. The AA philosophy stresses in particular the practice of making restitution, the necessity to help other alcoholics, trust in a higher power, the group confessional, and the belief that the alcoholic alone is powerless over alcohol. The AA philosophy also embodies the 24-h plan, in which the alcoholic strives to be abstinent for just a day at a time (a concept inspired by the Sermon on the Mount) as a means of facilitating the maintenance of sobriety. Although accurate statistics are lacking, it is said that about one-third of the members who express more than a passing interest in the program attain a state of long-sustained or permanent sobriety. Although the methods used by AA are not preferred by every patient, most who persist can benefit; in particular, the physician should not accept a patient's initial negative reaction as reason to abandon AA as a mode of treatment.

Finally, it should be noted that alcoholism is frequently associated with psychiatric disease of other type, particularly sociopathy and affective illness. In the latter case, the prevailing mood is far more often one of depression than of mania and is more often encountered in women, who are more apt to drink under these conditions than are men. In these circumstances, expert psychiatric help should be sought, preferably from someone who is also familiar with addictive diseases.

Chapter 43

DISORDERS OF THE NERVOUS SYSTEM DUE TO DRUGS AND OTHER CHEMICAL AGENTS

Neuropharmacology: General Principles

Drug–Nervous System Interactions

Bioavailability

Opiates and Synthetic Analgesic Drugs

Opioid Overdose

Opioid Addiction

Sedative-Hypnotic Drugs

Barbiturates

Chloral Hydrate

Benzodiazepines

Carbonic Acid Derivatives

Antipsychotic Drugs

Phenothiazines

Antidepressants

Monoamine Oxidase Inhibitors

Tricyclic Antidepressants

Serotonin Reuptake Inhibitors and Related Drugs

Lithium

Stimulants

Hallucinogens

Cocaine

Marijuana

Mescaline, LSD, and Psilocybin

Phencyclidine (“Angel Dust” and “Ecstasy”)

Disorders Due to Bacterial Toxins

Tetanus

Diphtheria

Botulism

Poisoning Due to Plants, Venoms, Bites, and Stings

Ergotism

Lathyrism

Mushroom Poisoning

Buckthorn Poisoning

Neurotoxin Fish Poisoning (Ciguatera)

Venoms, Bites, and Stings

Tick Paralysis

Heavy Metals

Lead

Arsenic

Manganese

Mercury

Phosphorus and Organophosphate Poisoning

Thallium

Other Metals

Industrial Toxins

Antineoplastic and Immunosuppressive Agents

Vincristine

Procarbazine

L-Asparaginase

5-Fluorouracil

Methotrexate

Cisplatin

Paclitaxel and Docetaxel

The Nitrosoureas

Cytarabine (Ara-C)

Cyclosporine and Tacrolimus (FK-506)

Thalidomide

Antibiotics and Other Drugs

Chapter References

Subsumed under this title is a diverse group of disorders of the nervous system that result from introduction into the body of drugs and other injurious or poisonous substances. A drug can be broadly defined as *any chemical agent that affects living processes*, but for purposes of this chapter, the discussion is limited to such drugs as are useful in the prevention and treatment of diseases of the nervous system. In addition, the neurologist must be concerned with the myriad of chemical agents that have no therapeutic utility but may adversely affect the nervous system; they abound in the environment as household products, insecticides, industrial solvents, and other poisons, the toxic effects of which must be recognized and treated. Also included among neurotoxins are those generated by bacteria and other infectious agents as well as several found in nature, such as marine toxins and agents elaborated by living animals. These are designated as *endogenous* if they arise within the body and *exogenous* if introduced from outside. Such a division cannot always be sharply drawn, as in the case of toxins produced by certain bacteria after being introduced from the outside (e.g., tetanus).

It would hardly be possible within the confines of this chapter to discuss with any degree of completeness the innumerable drugs and toxins that affect the nervous system. The interested reader is referred to a number of comprehensive monographs and references listed at the end of this chapter. In addition, an up-to-date handbook of pharmacology and toxicology should be part of the library of every physician.

The scope of this chapter is also limited because the therapeutic and adverse effects of many drugs are considered elsewhere in this volume, in relation to particular symptoms and diseases. Thus, the toxic effects of ethyl, methyl, amyl, and isopropyl alcohol, as well as ethylene glycol, are discussed in [Chap. 42](#), on alcohol. The adverse effects of antibiotics on cochlear and vestibular function and on neuromuscular transmission are discussed in [Chap. 15](#) and [Chap. 53](#), respectively. Many of the undesirable side effects of the common drugs used in the treatment of extrapyramidal motor symptoms, pain, headache, convulsive seizures, sleep disorders, psychiatric illnesses, and so forth are considered in the chapters dealing with each of these disorders. Cyanide and carbon monoxide poisoning are discussed in relation to anoxic encephalopathy ([Chap. 40](#)). A number of therapeutic agents that damage the peripheral nerves (e.g., cisplatin, disulfiram, vincristine, dapsone, etc.) are mentioned in this chapter but are discussed further in [Chap. 46](#), and those affecting muscle, in [Chap. 51](#).

The presentation of this subject is introduced by some general remarks on the action of drugs on the nervous system and then focuses on the more common categories of drugs and chemical agents that affect the nervous system selectively or predominantly. The references at the end of the chapter are listed in relation to each of these categories:

1. Action of drugs on the nervous system: general principles
2. The addicting drugs: opiates and synthetic analgesics
3. Sedative-hypnotic drugs

4. Antipsychotic drugs
5. Antidepressant drugs
6. Stimulants
7. Psychoactive drugs
8. Bacterial toxins
9. Plant poisons, venoms, bites, and stings
10. Heavy metals
11. Industrial toxins
12. Antineoplastic and immunosuppressive agents
13. Thalidomide
14. Aminoglycoside antibiotics (ototoxicity) and penicillin derivatives (seizures)
15. Cardioactive agents (beta blockers, digitalis derivatives, amiodarone)

NEUROPHARMACOLOGY: GENERAL PRINCIPLES

Of primary importance is the manner in which a therapeutic agent, specifically its chemical structure, affects the biochemistry and physiology of neurons and their supporting elements (*pharmacodynamics*). The rational use of any drug also requires a knowledge of the best route of administration, the drug's absorption characteristics, its distribution in the nervous system and other organs, and its biotransformations and excretion (*pharmacokinetics*). Since every drug, if given in excess, has some adverse effects, therapeutics and toxicology are inseparable.

Drug–Nervous System Interactions

In no other field of neurology is it more apparent that all systems of neurons are not identical. Each has its own vulnerabilities to particular drugs and toxic agents. This principle, originally enunciated by O. and C. Vogt in their theory termed *pathocllisis*, has been elegantly confirmed by tracing chemical molecules to specific aggregates of neurons. Thus, pathocllisis explains the preferential effects of anesthetics on the neurons of the upper brainstem reticular formation, which, with its diffuse cortical connections, underlies consciousness. There are examples not only of certain groups of nerve cells being destroyed by a particular agent but also of their function and presumably particular parts of their structure being altered. Drugs may be targeted to the terminal axons, dendrites, neurofilaments, or receptors on pre- and postsynaptic surfaces of neurons or to certain of their metabolic activities, whereby they synthesize and release neurotransmitters or maintain their cellular integrity by the synthesis of RNA, DNA, and other proteins. Parkinson disease and the neurotoxin 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) are excellent examples of pathocllisis, in which a disease process and a synthetic toxin effect a progressive loss of melanin-bearing nigral neurons and a depletion of their neurotransmitter, dopamine. Evidence is also accumulating about the mechanisms by which drugs and toxins can alter particular steps in the formation, storage in presynaptic vesicles, release, uptake, catabolism, and resynthesis of neurotransmitters such as dopamine, serotonin, norepinephrine, acetylcholine, and other catecholamines. Johnston and Silverstein have summarized current views of how these transmitters and modulating agents, by attaching to receptors at neuronal synapses, are able to increase or decrease the permeability of ion channels and stimulate or inhibit second cytoplasmic messengers. Drugs such as L-dopa, tryptophan, and choline are believed to act by enhancing the synthesis of dopamine, serotonin, and acetylcholine, respectively. Baclofen is thought to modulate the release of gamma-aminobutyric acid (GABA), the main inhibitory transmitter in the central nervous system (CNS). Clonidine prevents the release of norepinephrine; botulinus toxin has a similar effect on acetylcholine, and tetanus toxin on GABA in Renshaw cells of the spinal cord. Amantadine, an antiviral agent, is thought to promote the release of dopamine, and guanidine, of acetylcholine. Benzodiazepines, bromocriptine, and methylphenidate are viewed as receptor agonists; the phenothiazines and anticholinergics act as receptor antagonists. Certain drugs enhance the activity of neurotransmitters by inhibiting their reuptake, as, for example, the antidepressant class of drugs, which has a relatively selective influence on the reuptake of serotonin. One must not assume that these are the exclusive modes of action of each of these drugs, but these new data are instructive and indicate the future direction of neuropharmacology.

Lacking still is information about the precise mechanisms of even the most common anesthetics. It is assumed that by their lipid solubility they alter the physicochemical properties of the cell membrane and thus impair the activities of the membrane receptor systems that regulate ion channels, particularly the chloride and calcium channels. Antiviral agents such as acyclovir possibly block viral replication in nerve and glial cells once the inactive form of the drug is activated by thymidine kinase in these cells. A similar mode of action is postulated for azidothymidine (AZT), used in the treatment of acquired immunodeficiency syndrome (AIDS).

Bioavailability

A majority of drugs that act on the nervous system are ingested; factors that govern their intestinal absorption must, therefore, be taken into account. Small molecules usually enter the plasma by diffusion, larger ones by pinocytosis. The substances with which the drugs are mixed (excipients); the presence of food, other drugs, or intestinal diseases; and the age of the patient all influence the rate of absorption and blood concentrations. Different calculations are necessary for intramuscular, subcutaneous, and intrathecal routes of administration. To some extent, the solubilities of drugs (in lipid or water) determine the routes by which they can be given; some drugs, such as morphine, can be administered by manifold routes. Carried in the blood, the drug (or toxin) reaches many tissues, including the nervous system; protein binding in the plasma has an important influence on distribution. Many drugs and toxic substances bind to serum albumin and other serum proteins, limiting the availability of the ionized form. The common drug and toxin transformations involve hydroxylation, deamination, oxidation, and dealkylation, which enhance their solubility and elimination by the kidney. Most of these catalytic processes occur in liver cells and utilize multiple enzymes.

To enter the extracellular compartment of the nervous system, the drug or toxic agent in question must transgress the tight capillary endothelial barrier (blood-brain barrier) and the barrier between the blood and cerebrospinal fluid (CSF). Intrathecal injection circumvents these barriers, but then the agent tends to concentrate in the immediate subpial and subependymal regions. The process of movement from plasma to brain is by diffusion through capillaries or by facilitated transport. The solubility characteristics of the drug determine its rate of diffusion.

In the following exposition on neurotoxins, the reader will be repeatedly exposed to a number of novel phenomena: *tolerance* (lessening effect of increasing dose), *dependence* and *addiction* (insatiable need), *habituation*, *drug-seeking behaviors*, and *abstinence* and associated *withdrawal effects*. These were described in [Chap. 42](#) on alcoholism and are further elaborated below. Particularly difficult in reference to drugs such as nicotine is the separation of habituation from addiction, i.e., of psychologic dependence from physical dependence (see further on).

To make intelligent use of any of the pharmacologic agents described below, the neurologist must know about their pharmacodynamic and pharmacokinetic properties. The few examples given above are intended to provide a glimpse of the complex interactions between chemical agents and the cells of the nervous system. For more specific information, the reader is referred to *The Biochemical Basis of Neuropharmacology* by Cooper, Bloom, and Roth, an excellent text that we have consulted through its seven editions. The continued elucidation of the modes of action of the several hundred drugs and toxins that act on the nervous system promises to yield important information about the biochemical physiology of neurons and opens for study an inviting field of experimental neuropharmacology.

OPIATES AND SYNTHETIC ANALGESIC DRUGS

The opiates, strictly speaking, include all the naturally occurring alkaloids in opium, which is prepared from the seed capsules of the poppy *Papaver somniferum*. For clinical purposes, the term *opiate* refers only to the alkaloids that have a high degree of analgesic activity, i.e., morphine and codeine. The terms *opioia* and *narcotic-analgesic* designate drugs with actions similar to those of morphine. Compounds that are chemical modifications of morphine include diacetylmorphine, or heroin (still the most commonly abused opioid), hydromorphone (Dilaudid), codeine, hydrocodone (Hydrocet), oxymorphone (Numorphan), and oxycodone (Percodan). A second class of opioids comprises the purely synthetic analgesics: meperidine (Demerol) and its congeners, notably fentanyl (Sublimaze), methadone (Dolophine), levorphanol (Levo-Dromoran), propoxyphene (Darvon), pentazocine (Talwin), diphenoxylate (the main component of Lomotil), and phenazocine (Prinadol). The synthetic analgesics are similar to the opiates, in both their pharmacologic effects and patterns of abuse, the differences being mainly quantitative.

The clinical effects of the opioids are considered from two points of view: (1) acute poisoning and (2) addiction.

Opioid Overdose

Because of the common and particularly the illicit use of opioids, poisoning is a frequent occurrence. This happens as a result of ingestion or injection with suicidal intent, errors in the calculation of dosage, the use of a substitute or contaminated street product, or unusual sensitivity. Children exhibit an increased susceptibility to opioids, so that relatively small doses may prove toxic. This is true also of adults with myxedema, Addison disease, chronic liver disease, or pneumonia. Acute

poisoning may also occur in addicts who are unaware that available opioids vary greatly in potency and that tolerance for opioids declines quickly after the withdrawal of the drug; upon resumption of the habit, a formerly well-tolerated dose can be fatal.

Varying degrees of unresponsiveness, shallow respirations, slow respiratory rate (e.g., two to four per minute) or periodic breathing, pinpoint pupils, bradycardia, and hypothermia are the well-recognized clinical manifestations of acute opioid poisoning. In the most advanced stage, the pupils dilate, the skin and mucous membranes become cyanotic, and the circulation fails. The immediate cause of death is usually respiratory depression, with consequent asphyxia. Patients who suffer a cardiorespiratory arrest are sometimes left with all the known residua of anoxic encephalopathy. Others who recover from coma may occasionally reveal a hemiplegia, presumably due to vascular occlusion. Mild degrees of intoxication are betrayed by anorexia, nausea, vomiting, constipation, and loss of sexual interest.

Treatment This consists of the administration of naloxone (Narcan), a specific antidote to the opiates and also to the synthetic analgesics. The dose of naloxone is 0.7 mg/70 kg body weight *intravenously*, repeated if necessary once or twice at 5-min intervals. In cases of opioid poisoning, the improvements in circulation and respiration and reversal of miosis are usually dramatic. In fact, failure of naloxone to produce such a response should cast doubt on the diagnosis of opioid intoxication. If an adequate respiratory and pupillary response to naloxone is obtained, the patient should be observed carefully for 24 h and further doses of naloxone (50 percent higher than the ones previously found effective) should be given *intramuscularly* as often as necessary. Naloxone has little direct effect on consciousness, however, and the patient may remain drowsy for many hours. This is not harmful provided that respiration is well maintained. Gastric lavage is a useful measure if the drug was taken orally. This procedure may be efficacious many hours after ingestion, since one of the toxic effects of opioids is severe pylorospasm and ileus, which causes much of the drug to be retained in the stomach.

Once the patient regains consciousness, complaints such as pruritus, sneezing, tearing, piloerection, diffuse body pains, yawning, and diarrhea may appear. These are the recognizable symptoms of the opioid abstinence, or withdrawal, syndrome, described below. An antidote therefore must be used with great caution in an addict who has taken an overdose of opioid, because in this circumstance it may precipitate withdrawal phenomena. Nausea and severe abdominal pain, due presumably to pancreatitis (from spasm of the sphincter of Oddi), are other troublesome symptoms of opiate use or withdrawal. Seizures are rare.

Opioid Addiction

Just 30 to 35 years ago there were an estimated 60,000 persons addicted to narcotic drugs in the United States, exclusive of those who were receiving drugs because of incurable painful diseases. This represented a relatively small public health problem in comparison with the abuse of alcohol and barbiturates. Moreover, opioid addiction was of serious proportions in only a few cities—New York, Chicago, Los Angeles, Washington, and Detroit. Since the late 1960s, a remarkable increase in opioid (mainly heroin) addiction has taken place. The precise number of opioid addicts is not known but is currently estimated by the Drug Enforcement Administration to be more than 500,000 (a disproportionate number in New York and a few other large cities). The prevalence and patterns of opioid abuse have been reviewed by Brust.

Etiology and Pathogenesis A number of factors—socioeconomic, psychologic, and pharmacologic—contribute to the genesis of opioid addiction. In our culture, the most susceptible subjects are young men or delinquent youths living in the economically depressed areas of large cities, but significant numbers are now found in the suburbs and in small cities as well. The onset of opioid use is usually in adolescence, with a peak at 17 to 18 years; fully two-thirds of addicts start using the drugs before the age of 21. Almost 90 percent of addicts engage in criminal activity, often to obtain their daily ration of drugs, but most of them have a history of arrests or convictions antedating their addiction. Also, many of them have psychiatric disturbances, conduct disorder and sociopathy being the most common. Monroe and colleagues, using the Lexington Personality Inventory, examined a group of 837 opioid addicts and found evidence of antisocial personality in 42 percent, emotional disturbance in 29 percent, and thinking disorder in 22 percent; only 7 percent were free of such disorders. Obviously, vulnerability to addiction is not confined to one personality type.

Association with addicts is the apparent explanation for beginning addiction. One addict recruits another person into addiction, and the new recruit does likewise. In this sense opioid addiction is contagious, and as a result of this pattern, heroin addiction has attained epidemic proportions. A small, almost insignificant proportion of addicts are introduced to drugs by physicians in the course of an illness. One seldom hesitates, therefore, to prescribe opiates to patients with chronic pain (e.g., cancer pain) because of the risk of addiction.

Opioid addiction consists of three recognizable phases: (1) episodic intoxication, or “euphoria,” (2) pharmacogenic dependence or drug-seeking behavior (addiction), and (3) the propensity to relapse after a period of abstinence.

Some of the symptoms of opioid intoxication have already been considered. In patients with severe pain or pain-anticipatory anxiety, the administration of opioids produces a sense of unusual well-being, a state that has traditionally been referred to as *morphine euphoria*. It should be emphasized that only a negligible proportion of such persons continue to use opioids habitually after their pain has subsided. The vast majority of potential addicts are not suffering from painful illnesses at the time they initiate opioid use, and the term *euphoria* is not an apt description of the initial effects. These persons, as indicated above, are mainly teenagers who self-administer opioids under the tutelage of their peers. They learn, after several repetitions, to recognize a “high,” despite the subsequent recurrence of unpleasant, or *dysphoric*, symptoms (nausea, vomiting, faintness as the drug effect wanes). The repeated self-administration of the drug (“reinforcement” in the language of operant psychology) is the most important factor in the genesis of *addiction*. Regardless of how one characterizes the state of mind that is produced by episodic injection of the drug, the individual quickly discovers the need to increase the dose in order to obtain the original effects. Although the initial effects may not be fully recaptured, the progressively increasing dose of the drug does relieve the discomfort that arises as the effects of each injection wear off. In this way a new *pharmacogenically induced* need is developed, and the use of opioids becomes self-perpetuating. At the same time a marked degree of *tolerance* is produced, so that enormous amounts of drugs, e.g., 5000 mg of morphine daily, have eventually been administered without the development of toxic symptoms.

The pharmacologic criteria of addiction, as indicated in the chapter on alcoholism, are *tolerance* and *physical dependence*. The latter refers to the symptoms and signs that become manifest when the drug is withdrawn following a period of continued use. These symptoms and signs constitute a specific clinical state, termed *the abstinence* or *withdrawal syndrome* (see below). The mechanisms that underlie the development of tolerance and physical dependence are not fully understood. However, it is known that opioids activate the brain's opioid antinociceptive system (enkephalins, dynorphins, endorphins) and specific opioid receptors, which are located at different levels of the nervous system (these are described in [Chap. 8](#), on pain; see also the review of Fields).

The Opioid Abstinence Syndrome The intensity of the *abstinence* or *withdrawal* syndrome depends on the dose of the drug and the duration of addiction. The onset of abstinence symptoms in relation to the last exposure to the drug, however, is related to the pharmacologic half-life of the agent. With morphine, the majority of individuals receiving 240 mg daily for 30 days or more will show moderately severe abstinence symptoms following withdrawal. Mild signs of opiate abstinence can be precipitated by narcotic antagonists in persons who have taken as little as 15 mg of morphine or an equivalent dose of methadone or heroin three times daily for 3 days.

The abstinence syndrome that occurs in the morphine addict may be taken as the prototype of the opioid group. The first 8 to 16 h of abstinence usually pass asymptotically. At the end of this period, yawning, rhinorrhea, sweating, piloerection, and lacrimation become manifest. Mild at first, these symptoms increase in severity over a period of several hours and then remain constant for several days. The patient may be able to sleep during the early abstinence period but is restless, and thereafter insomnia remains a prominent feature. Dilatation of the pupils, recurring waves of gooseflesh, and twitchings of the muscles appear. The patient complains of aching in the back, abdomen, and legs and of “hot and cold flashes”; he frequently asks for blankets. At about 36 h the restlessness becomes more severe, and nausea, vomiting, and diarrhea usually develop. Temperature, respiratory rate, and blood pressure are slightly elevated. All these symptoms reach their peak intensity 48 to 72 h after withdrawal and then gradually subside. The opioid abstinence syndrome is rarely fatal (it is life-threatening only in infants). After 7 to 10 days, the clinical signs of abstinence are no longer evident, although the patient may complain of insomnia, nervousness, weakness, and muscle aches for several more weeks, and small deviations of a number of physiologic variables can be detected with refined techniques for up to 10 months (protracted abstinence).

Habituation, also designated as emotional or psychologic *dependence*, refers to the substitution of drug-seeking activities for all other aims and objectives in life and is the essence of addiction. It is this feature (craving or “purposive” abstinence changes) that fosters relapse to the use of the drug long after the physiologic (“nonpurposive”) abstinence changes seem to have disappeared. The cause for relapse is not fully understood. Theoretically, fragments of the abstinence syndrome may remain as a conditioned response, and these abstinence signs may be evoked by the appropriate environmental stimuli. Thus, when a “cured” addict is in a situation where narcotic drugs are readily available or in a setting that was associated with the initial use of drugs, the incompletely extinguished drug-seeking behavior may reassert itself.

The characteristics of addiction and of abstinence are qualitatively similar with all drugs of the opiate group as well as the related synthetic analgesics. The

differences are quantitative and are related to the differences in dosage, potency, and length of action. Heroin is two to three times more potent than morphine, but the heroin withdrawal syndrome encountered in hospital practice is usually mild in degree because of the low dosage of the drug in the street product. Dilaudid (hydromorphone) is more potent than morphine and has a shorter duration of action; hence the addict requires more doses per day, and the abstinence syndrome comes on and subsides more rapidly. Abstinence symptoms from codeine, while definite, are less severe than those from morphine. The addiction liabilities of propoxyphene are negligible. Abstinence symptoms from methadone are less intense than those from morphine and do not become evident until 3 or 4 days after withdrawal; for these reasons methadone can be used in the treatment of morphine dependency (see further on). Meperidine addiction is of particular importance because of its high incidence among physicians and nurses. Tolerance to the drug's toxic effects is not complete, so that the addict may show tremors, twitching of muscles, confusion, hallucinations, and sometimes convulsions. Signs of abstinence appear 3 to 4 h after the last dose and reach their maximum intensity in 8 to 12 h, at which time they may be worse than those of morphine abstinence.

As to the biologic basis of tolerance and physical dependence, our understanding is still very limited. Experiments in animals have provided the first insights into the neurotransmitter and neuronal systems involved. As a result of microdialysing opiates and their antagonists into central brain structures, it has been tentatively concluded that mesolimbic structures, particularly the nucleus accumbens, ventral tegmentum of the midbrain, and locus ceruleus are activated or depressed under conditions of repeated opiate exposure. Thus, chronic opiate exposure increases the levels of certain intracellular messengers (possibly G proteins) that drive cyclic-AMP activity in the locus ceruleus and in the nucleus accumbens; blocking the expression of these proteins markedly increases the self-administration of opiates by addicted rats. As with alcohol addiction, certain subtypes of the serotonin and dopamine receptors in limbic structures have been implicated. These incipient insights into the neurochemical mechanism of addiction have been reviewed by Hyman and by Nestler and Aghajanian.

Diagnosis of addiction is usually made when the patient admits to using and needing drugs. Should the patient conceal this fact, one relies on collateral evidence such as miosis, needle marks, emaciation, abscess scars, or chemical analyses. Meperidine addicts are likely to have dilated pupils and twitching of muscles. The finding of morphine or opiate derivatives (heroin is excreted as morphine) in the urine is confirmatory evidence that the patient has taken or has been given a dose of such drugs within 24 h of the test. The diagnosis of opiate addiction is at once apparent when the treatment of acute opiate intoxication precipitates a characteristic abstinence syndrome.

Treatment of the Opioid Abstinence Syndrome (Physical Dependence) This consists of substituting methadone for opioid, in the ratio of 1 mg methadone for 3 mg morphine, 1 mg heroin, or 20 mg meperidine. Since methadone is long-acting and effective orally, it need be given only twice daily by mouth—10 to 20 mg per dose being sufficient to suppress abstinence symptoms. After a stabilization period of 3 to 5 days, this dosage of methadone is reduced and the drug is withdrawn over a similar period of time. An alternative but less effective method is to use clonidine, a drug that counteracts most of the noradrenergic withdrawal symptoms (5 mg/kg twice a day for a week); hypotension may be a problem, however (Jasinski et al).

Recently, the use of rapid detoxification under general anesthesia has become popular in a number of centers as a means of treating opiate addiction. The technique consists of administering increasing doses of opioid receptor antagonists (naloxone or naltrexone) over several hours while the autonomic and other features of the withdrawal syndrome are suppressed by the infusion of propofol or a similar anesthetic, supplemented by intravenous fluids. Medications such as clonidine and sedatives are given in the immediate postanesthetic period. The addict is instructed to continue taking naltrexone for several days or weeks, a practice adopted from one of the outpatient treatments for addiction described below. There are substantial risks involved in the procedure, and a few deaths have occurred. Furthermore, a number of patients continue to manifest signs of withdrawal after the procedure and require continued hospitalization. There are as yet no careful studies of the efficacy of this procedure, particularly in regard to conferring long-term abstinence.

Treatment of Habituation (Psychologic Dependence) This is far more demanding than the treatment of opioid withdrawal and can be best accomplished in special facilities and programs that are devoted wholly to the problem and are available in most communities. The most effective facilities have been the ambulatory methadone maintenance clinics, where more than 100,000 former heroin addicts are participating in rehabilitation programs approved by the Food and Drug Administration. Methadone, in a dosage of 60 to 100 mg daily (sufficient to suppress the craving for heroin), is given under supervision day by day (less often with long-acting methadone) for months or years. Various forms of psychotherapy and social service counseling (often by former heroin addicts) are integral parts of the program.

The results of methadone treatment are difficult to assess and vary considerably from one program to another. Even the most successful programs suffer an attrition rate of about 25 percent when they are evaluated after several years. Of the patients who remain, the majority achieve a high degree of social rehabilitation, i.e., they are gainfully employed and no longer engage in criminal behavior or prostitution. Another notable achievement of the methadone maintenance programs has been the reduction in the number of chronic intravenous drug abusers. This is quite important, for one-quarter of the latter group are seropositive for human immunodeficiency virus (HIV) and are the chief source of transmission of AIDS to newborns and to the heterosexual nonaddicted population.

The usual practice of methadone programs is to accept only addicts over the age of 16 years with a history of heroin addiction for at least 1 year. This leaves many adolescent addicts untreated. The number of addicts who can fully withdraw from methadone and maintain a drug-free existence is very small. This means that the large majority of addicts now enrolled in methadone programs are committed to an indefinite period of methadone maintenance, and the effects of such a regimen are uncertain.

An alternative method of ambulatory treatment of the opiate addict involves the use of narcotic antagonists, of which naloxone and naltrexone are the best known. Naltrexone is favored because it has a longer effect than naloxone, is almost free of agonist effects, and can be administered orally. Good results have also been achieved with cyclazocine in a small number of highly motivated patients; this drug is administered orally in increasing amounts until a dosage of 2 mg/70 kg body weight is attained. The drug is taken twice daily (for 2 to 6 weeks) and is then withdrawn slowly.

More recently, interest has centered on the use of buprenorphine for the treatment of heroin (and cocaine) abuse. Buprenorphine is unique in that it has both opioid agonist and antagonist properties; it therefore mutes the effect of withdrawal and serves also as an aversive agent, like naltrexone. In addition, there is evidence, based on animal experiments and the treatment of small numbers of addicts, that it may be useful for the treatment of dual dependence on cocaine and opiates (see [Mello and Mendelson](#)). Buprenorphine has the additional advantage of being administered as a sublingual tablet. The FDA has recently approved its use.

Medical and Neurologic Complications of Opioid Use In addition to the toxic effects of the opioid itself, the addict may suffer a variety of neurologic and infectious complications resulting from the injection of contaminated adulterants (quinine, talc, lactose, powdered milk, and fruit sugars) and of various infectious agents (injections administered by unsterile methods). The most important of these is HIV infection, but septicemia and endocarditis and viral hepatitis may also occur. Particulate matter that is injected with heroin or a vasculitis that is induced by chronic heroin abuse may cause *occlusion of cerebral arteries*, with hemiplegia or other focal cerebral signs. *Amblyopia*, due probably to the toxic effects of quinine in the heroin mixtures, has been reported, as well as *transverse myelopathy* and several types of *peripheral neuropathy*. The spinal cord disorder expresses itself clinically by the abrupt onset of paraplegia with a level on the trunk below which motor function and sensation are lost or impaired and by urinary retention. Pathologically, there is an acute necrotizing lesion involving both gray and white matter over a considerable vertical extent of the thoracic and occasionally the cervical cord. In some cases a myelopathy has followed the first intravenous injection of heroin after a prolonged period of abstinence. We have seen several cases of cervical myelopathy from heroin-induced stupor that had led to a prolonged period of immobility with the neck hyperextended over the back of a chair or sofa. We have also observed several instances of a progressive cerebral leukoencephalopathy attributed to heroin use, similar to ones that occurred in Amsterdam in the 1980s, the result of inhalation of heroin pyrolysate or an adulterant thereof ([Wolters](#) et al and [Tan](#) et al). In our cases the white matter changes were concentrated in the posterior portions of the hemispheres and in the internal capsules. A similar leukoencephalopathy has also been observed in cocaine users, in some of whom a hypertensive encephalopathy or an adrenergic-induced vasculopathy may have played a role. Damage to single peripheral nerves at the injection site and from compression is a relatively common occurrence. Bilateral compression of the sciatic nerves, caused by sitting or lying for a prolonged period in a stuporous state or in the lotus position while “stoned,” has been observed in several of our patients. In sciatic compression of this sort, the peroneal branch is more affected than the tibial, causing foot drop with less in the way of weakness of plantar flexion. More difficult to understand is the involvement of other individual nerves, particularly the radial nerve, and painful affection of the brachial plexus, apparently unrelated to compression and remote from the sites of injection.

An acute generalized *myonecrosis* with myoglobinuria and renal failure has been ascribed to the intravenous injection of adulterated heroin. Brawny edema and fibrosing myopathy (Volkmann contracture) are the sequelae of venous thrombosis resulting from the administration of heroin and its adulterants by the intramuscular and subcutaneous routes. Occasionally there may be massive swelling of an extremity into which heroin had been injected subcutaneously or intramuscularly; infection and venous thrombosis appear to be involved in its causation.

The diagnosis of drug addiction or the suspicion of this diagnosis should always raise the prospect of infectious complications, particularly AIDS, syphilis, abscesses and cellulitis at injection sites, septic thrombophlebitis, hepatitis, and periarteritis. Tetanus, endocarditis (due mainly to *Staphylococcus aureus*), spinal epidural

abscess, meningitis, brain abscess, and tuberculosis have occurred less frequently.

SEDATIVE-HYPNOTIC DRUGS

This class of drugs, also referred to as depressants, consists of two main groups. The first includes the barbiturates and chloral hydrate. These drugs are now little used, having been largely replaced by a second group, comprising *meprobamate* and other glycerol derivatives and the *benzodiazepines*, the most important of which are chlordiazepoxide (Librium), lorazepam (Ativan), alprazolam (Xanax), and diazepam (Valium). Closely related are the non-benzodiazepine hypnotics, typified by zolpidem (Ambien). The advantages of the benzodiazepine drugs are their *relatively* low toxicity and addictive potential and their minimal interactions with other drugs.

Barbiturates

Despite the marked reduction in the medical use of barbiturates during the past three decades, the improper use of these drugs—particularly their nonmedical and illicit use—still leads to suicide, accidental death, and addiction. In the past, about fifty barbiturates were marketed for clinical use, but only the following are now encountered with any regularity: pentobarbital (Nembutal), secobarbital (Seconal), amobarbital (Amytal), thiopental (Pentothal), barbital (Veronal), and phenobarbital (Luminal). The first three are the ones most commonly abused.

Mechanism of Action All the common barbiturates are derived from barbituric acid; the differences between them depend on variations in the side chains of the parent molecule. The potency of each drug is a function of the ionization constant and lipid solubility. The higher its lipid solubility, the greater the drug's potency and the quicker and briefer its action. The lowering of plasma pH increases the rate of entry of the ionized form into the brain. The action of barbiturates is to suppress neuronal transmission, presumably by enhancing GABA inhibition at pre- and postsynaptic receptor sites, and to reduce excitatory postsynaptic potentials. The major points of action in the CNS are similar to those of alcohol and other coma-producing drugs; impaired consciousness or coma relates to inactivation of neurons in the reticular formation of the upper brainstem. The liver is the main locus of drug metabolism, and the kidney is the locus of elimination. All the barbiturates are similar pharmacologically and differ only in the speed of onset and duration of their action. The clinical problems posed by the barbiturates are different, however, depending on whether the intoxication is acute or chronic.

Acute Barbiturate Intoxication This results from the ingestion of large amounts of the drug, either accidentally or with suicidal intent. The latter is most frequently the act of a depressed person. The hysteric or sociopath may take an overdose as a suicidal gesture and become seriously intoxicated because of miscalculation or ignorance of the toxic dosage. Often the drug is taken while the individual is inebriated—a dangerous situation, since alcohol and barbiturate have an additive effect.

Diagnosis of Barbiturate Intoxication The symptoms and signs vary with the type and amount of drug as well as with the length of time that has elapsed since it was ingested. Pentobarbital and secobarbital produce their effects quickly, and recovery is relatively rapid. Phenobarbital induces coma more slowly, and its effects tend to be prolonged. The duration of action of these drugs can be judged by the hypnotic effect of an average oral dose. In the case of long-acting barbiturates, such as phenobarbital and barbital, the effect lasts 6 h or more; with the intermediate-acting drugs, amobarbital and aprobarbital, 3 to 6 h; and with the short-acting drugs, secobarbital and pentobarbital, less than 3 h. Most fatalities follow the ingestion of secobarbital, amobarbital, or pentobarbital. The ingestion by adults of more than 3.0 g of these drugs at one time will prove fatal unless intensive and skilled treatment is applied promptly. The potentially fatal dose of phenobarbital is 6 to 10 g. The lowest plasma concentration associated with lethal overdosage of phenobarbital or barbital is 60 mg/mL and that of amobarbital and pentobarbital is 10 mg/mL.

In regard to prognosis and treatment, it is useful to recognize three grades of severity of acute barbiturate intoxication. *Mild intoxication* follows the ingestion of approximately 0.3 g pentobarbital (Nembutal; the hypnotic dose in an unhabituated patient is 100 mg) or its equivalent. The patient is drowsy or asleep, although readily roused if called or shaken. The symptoms resemble those of alcohol intoxication. The patient thinks slowly, and there may be mild disorientation, lability of mood, impairment of judgment, slurred speech, drunken gait, and nystagmus. *Moderate intoxication* follows the ingestion of 5 to 10 times the oral hypnotic dose. The patient is stuporous, tendon reflexes are usually depressed or absent, and respirations are slow but not shallow. Corneal and pupillary reflexes are retained, with occasional exceptions. Usually the patient can be roused by vigorous manual stimulation; when awakened, he is confused and dysarthric and, after a few moments, drifts back into stupor. *Severe intoxication* occurs with the ingestion of 10 to 20 times the oral hypnotic dose. The patient cannot be roused by any means. Respiration is slow and shallow or irregular, and pulmonary edema and cyanosis may be present. The tendon reflexes are usually but not invariably absent. Most patients show no response to plantar stimulation, but in those who do, the responses are extensor. With deep coma, the corneal and gag reflexes may also be abolished. Ordinarily the pupillary light reflex is retained in severe intoxication and is lost only if the patient is asphyxiated; but in advanced cases, the pupils become miotic and poorly reactive, simulating opiate intoxication. At this point respiration is greatly depressed and oculocephalic and oculovestibular reflex responses are usually abolished. In the early hours of coma, there may be a phase of flexor or extensor posturing or rigidity of the limbs, hyperactive reflexes, ankle clonus, and extensor plantar signs; persistence of these signs indicates that anoxic damage has been added. The temperature may be subnormal, the pulse is thready and rapid, and the blood pressure is at shock levels.

There are few conditions other than barbiturate intoxication that cause a flaccid coma with small reactive pupils, hypothermia, and hypotension. A pontine hemorrhage may do so, but a hysterical trance or catatonic stupor presents the main problem in differential diagnosis. The use of gas and high-pressure liquid chromatography provides a reliable means of identifying the type and amount of barbiturate in the blood. A patient who has also ingested alcohol may be comatose with relatively low blood barbiturate concentrations. Contrariwise, the addicted (tolerant) patient may show only mild signs of intoxication with very high blood barbiturate concentrations.

The electroencephalogram (EEG) may also be useful in diagnosis. In mild intoxication, the normal activity is replaced by fast (beta) activity, in the range of 20 to 30 cycles per second, and is most prominent in the frontal regions. In more severe intoxication, the fast waves become less regular and interspersed with 3- to 4-per-second slow activity; in still more advanced cases, there are short periods of suppression of all activity, separated by bursts of slow (delta) waves of variable frequency. In extreme overdosage, all electrical activity ceases. This is one instance in which a “flat” EEG cannot be equated with brain death, and the effects are fully reversible unless anoxic damage has supervened.

Management In mild or moderate intoxication, recovery is the rule and vigorous treatment is not required. If the patient is unresponsive, special measures must be taken to maintain respiration and prevent infection. An endotracheal tube should be inserted, with suctioning as necessary. Any risk of respiratory depression or underventilation requires the use of a positive- pressure respirator.

Hemodialysis or hemofiltration with charcoal may be used in profoundly comatose patients who fail to respond to the measures outlined above. They are particularly useful in cases of coma due to long-acting barbiturates and are mandatory if anuria or uremia has developed. Treatment with analeptic drugs (e.g., picrotoxin, pentylenetetrazol), which enjoyed a brief period of popularity, has been generally abandoned, since these drugs do not affect the rate of metabolism or the excretion of barbiturates.

Occasionally, in the case of a barbiturate addict who has taken an overdose of the drug, recovery from coma is followed by the development of abstinence symptoms, as described below.

Barbiturate Addiction (Chronic Barbiturate Intoxication) Chronic barbiturate intoxication, like other drug addictions, tends to develop on a background of some psychiatric disorder, most commonly a depressive illness with symptoms of anxiety and insomnia. Addiction to alcohol or to opiates may predispose to barbiturate addiction. Alcoholics find that barbiturates effectively relieve their nervousness and tremor. They may then continue to take both alcohol and barbiturate, or the barbiturate may replace the alcohol. As with other drug addictions, the incidence of barbiturism is particularly high in individuals with ready access to drugs, such as physicians, pharmacists, and nurses.

The manifestations of barbiturism are much the same as those of alcohol intoxication. The barbiturate addict thinks slowly, exhibits increased emotional lability, and becomes untidy in dress and personal habits. The neurologic signs include dysarthria, nystagmus, and cerebellar incoordination. If the dosage is elevated rapidly, the signs of moderate or severe intoxication, as described above, become manifest.

A characteristic feature of chronic barbiturate intoxication is the development of tolerance, sometimes striking in degree. The average addict ingests about 1.5 g of a potent barbiturate daily and does not manifest signs of severe intoxication unless this amount is exceeded. Tolerance to barbiturates does not develop as rapidly as to opiates. Most persons can ingest 0.4 g daily for as long as 3 months without developing major withdrawal signs (seizures or delirium). With a dosage of 0.8 g daily for a period of 2 weeks to 2 months, abrupt withdrawal will result in serious symptoms in the majority of patients (see below).

Barbiturate Abstinence, or Withdrawal, Syndrome Immediately following withdrawal, the patient seemingly improves over a period of 8 to 12 h, as the symptoms of

intoxication diminish. Then a new group of symptoms develops, consisting of nervousness, tremor, insomnia, postural hypotension, and weakness. With chronic phenobarbital or barbitol intoxication, withdrawal symptoms may not become apparent until 48 to 72 h after the final dose. Generalized seizures with loss of consciousness may occur, usually between the second and fourth days of abstinence but occasionally as long as 6 or 7 days after withdrawal. There may be a single seizure, several seizures, or, rarely, status epilepticus. Characteristically, in the withdrawal period, there is a greatly heightened sensitivity to photic stimulation, to which the patient responds with myoclonus or a seizure accompanied by paroxysmal changes in the EEG. The convulsive phase may be followed directly by a delusional-hallucinatory state or a full-blown delirium indistinguishable from delirium tremens, or a varying degree of improvement may follow the seizures before the delirium becomes manifest. Death has been reported under these circumstances. The abstinence syndrome may occur in varying degrees of completeness; some patients have seizures and recover without developing delirium, and others have a delirium without preceding seizures. The abrupt onset of seizures or an acute psychosis in adult life should always raise the suspicion of addiction to barbiturates or other sedative-hypnotic drugs.

Treatment of Chronic Barbiturate Intoxication This should always be carried out in the hospital. If the diagnosis of addiction is made before signs of abstinence have appeared, the “stabilization dosage” should first be determined. This is the amount of short-acting barbiturate required to produce mild symptoms of intoxication (nystagmus, slight ataxia, and dysarthria). Usually 0.2 g of pentobarbital given orally every 6 h is sufficient for this purpose. Then a gradual withdrawal of the drug is undertaken, 0.1 g daily, the reduction being stopped for several days if abstinence symptoms appear. In this way, a severely addicted person can be withdrawn in 14 to 21 days. The patient who presents with severe withdrawal symptoms, such as seizures, is given 0.3 to 0.5 g of phenobarbital intramuscularly and then enough to maintain a state of mild intoxication. Most other anticonvulsant medicines are ineffective against barbiturate withdrawal convulsions. Withdrawal should then be carried out as indicated above. If the abstinence symptoms are not severe, it is not necessary to reintoxicate the patient, but treatment can proceed along the lines laid down for other forms of delirium and confusion. After recovery has taken place, whether from acute or chronic intoxication, the psychiatric problem requires evaluation and an appropriate plan of therapy.

Chloral Hydrate

This is the oldest and one of the safest, most effective, and most inexpensive of the sedative-hypnotic drugs. After oral administration, chloral hydrate is reduced rapidly to trichloroethanol, which is responsible for the depressant effects on the CNS. A significant portion of the trichloroethanol is excreted in the urine as the glucuronide, which may give a false-positive test for glucose.

Tolerance and addiction to chloral hydrate develop only rarely; for this reason it is an appropriate medication for the management of insomnia, particularly the type that is associated with depression. Poisoning with chloral hydrate is a rare occurrence and resembles acute barbiturate intoxication except for the finding of miosis, which is said to characterize the former. Treatment follows along the same lines as for barbiturate poisoning. Death from poisoning is due to respiratory depression and hypotension; patients who survive may show signs of liver and kidney disease.

Paraldehyde, another member of this group of sedative drugs, is no longer being manufactured in the United States, and chloral hydrate is now available mainly as an elixir for pediatric use.

Benzodiazepines

With the introduction of chlordiazepoxide in 1960 and the benzodiazepine drugs that followed (particularly diazepam), the older sedative drugs (barbiturates, paraldehyde, chloral hydrate) have become virtually obsolete. Indeed, the benzodiazepines are the most commonly prescribed drugs in the world today. According to Hollister, 15 percent of all adults in the United States use a benzodiazepine at least once yearly and about half this number use the drug for a month or longer. As mentioned earlier, the benzodiazepines, compared with the older sedatives, have *relatively* minor hypnotic effects and low abuse potential and are *relatively* safe when taken in overdose.

The benzodiazepines have been used extensively for the treatment of anxiety and insomnia, and they are especially effective when the anxiety symptoms are severe. Also, they have been used to control overactivity and destructive behavior in children and the symptoms of alcohol withdrawal in adults. Diazepam is particularly useful in the treatment of delirious patients who require parenteral medication. The benzodiazepines possess anticonvulsant properties, and the intravenous use of diazepam, lorazepam, and midazolam is an effective means of controlling status epilepticus, as described on page 361. Diazepam in massive doses has been used with considerable success in the management of muscle spasm in tetanus and in “stiff man” syndrome (page 1569). Diazepam has been far less successful in the treatment of extrapyramidal movement disorders and dystonic spasms. Alprazolam (Xanax) has a central place in the treatment of panic attacks and other anxiety states, as an adjunct in some depressive illnesses, and in the behavioral disturbances in Alzheimer disease. It seems, however, to create more dependence than some of the others in its class.

Other important benzodiazepine drugs are flurazepam (Dalmane), triazolam (Halcion), chlorazepate (Tranxene), temazepam (Restoril), and other newer varieties, all widely used in the treatment of insomnia (page 414), and clonazepam (Klonopin), which is useful in the treatment of myoclonic seizures (pages 357 and 360) and intention myoclonus (page 110). Midazolam (Versed), a short-acting parenteral agent, is used frequently to achieve the brief sedation required for procedures such as MRI or endoscopy and is useful in the treatment of status epilepticus, but it is known to cause respiratory arrest on occasion. Lorazepam (Ativan) and oxazepam (Serax) are said to be preferable to other benzodiazepines in treating the elderly and those with impaired liver function. Many other benzodiazepine compounds have appeared in recent years, but a clear advantage over the original ones remains to be demonstrated ([Hollister](#); [Pirodsky and Cohn](#)). Zolpidem (Ambien) differs from the benzodiazepines structurally but is pharmacologically the same.

The benzodiazepine drugs, like barbiturates, have a depressant action on the CNS by binding to specific receptors on GABA inhibitory systems. The benzodiazepines act in concert with GABA to open chloride ion channels and hyperpolarize postsynaptic neurons and reduce their firing rate. The primary sites of their action are the cerebral cortex and limbic system, which accounts for their anticonvulsive and anxiolytic effects. While quite safe in the recommended dosages, they are far from ideal. They frequently cause unsteadiness of gait and drowsiness and at times hypotension and syncope, confusion, and impairment of memory, especially in the elderly. If taken in large doses, the benzodiazepines can produce a depression of the state of consciousness, resembling that of other sedative-hypnotic drugs but with less respiratory suppression and hypotension. *Flumazenil*, a specific pharmacologic antagonist of the CNS effects of benzodiazepines, rapidly but briefly reverses most of the symptoms and signs of benzodiazepine overdose. It acts by binding to CNS diazepam receptors and thereby blocking the activation of inhibitory GABAergic synapses. Flumazenil may also have diagnostic utility in cases of coma of unknown etiology and in hepatic encephalopathy (see page 1186).

Signs of physical dependence and true addiction, though relatively rare, undoubtedly occur in chronic benzodiazepine users, even in those taking therapeutic doses. The withdrawal symptoms are much the same as those that follow the chronic use of other sedative drugs (anxiety, jitteriness, insomnia, seizures) but may not appear until the third day after the cessation of the drug and may not reach their peak of severity until the fifth day ([Hollister](#)). In chronic benzodiazepine users, the gradual tapering of dosage over a period of 1 to 2 weeks minimizes the withdrawal effects.

Carbonic Acid Derivatives

These drugs are capable of modest depressant action and are effective in relieving mild degrees of nervousness, anxiety, and muscle tension. Meprobamate (Equanil, Miltown) is the best-known member of this group. It was the first of the new antianxiety drugs, a chemical variant of the weak and ineffective muscle relaxant mephenesin. With average doses (400 mg three or four times a day), the patient is able to function quite effectively; larger doses cause ataxia, drowsiness, stupor, coma, and vasomotor collapse.

Meprobamate has turned out to have the same disadvantages as the barbiturates, including death from overdosage. Addiction to meprobamate may occur, and if four or more times the daily recommended dose is administered over a period of weeks to months, withdrawal symptoms (including convulsions) may appear. Because of this tendency to produce physical dependence and other disadvantages (serious toxic reactions and a high degree of sedation), meprobamate and its congeners are now seldom used except illicitly.

Other Antianxiety Agents A new class of antianxiety agents, exemplified by the selective 5HT-2 serotoninergic agent buspirone (Buspar), is chemically and pharmacologically different from the benzodiazepines, barbiturates, or other sedatives. Because of its apparently reduced potential for abuse and tolerance, it is not a controlled pharmaceutical substance in the United States, but adverse interactions with MAO inhibitors are known; its use with other psychotropic drugs is still under investigation. It does not block the withdrawal syndrome due to other sedative-hypnotic drugs.

ANTIPSYCHOTIC DRUGS

In the mid-1950s, a large series of pharmacologic agents, originally referred to as tranquilizers (later, as psychotropic or neuroleptic drugs), came into prominent use—mainly for the control of schizophrenia, psychotic states associated with “organic brain syndromes,” and affective disorders (depression and manic-depressive disease). The mechanisms by which these drugs ameliorate disturbances of thought and affect in psychotic states are not fully understood, but presumably they act by blocking the postsynaptic dopamine receptors (there are four subtypes, termed D₁ through D₄) on neuronal membranes. The D₂ receptors are located mainly in the frontal cortex, hippocampus, and limbic cortex, and the D₁ receptors in the striatum. There is also some adrenergic blocking effect. The blockade of dopamine receptors in the striatum is probably responsible for the parkinsonian side effects of this entire class of drugs, and the blockade of another dopaminergic (tuberoinfundibular) system, for the increased prolactin secretion by the pituitary. The newer “atypical” antipsychotic drugs, typified by clozapine (Clozaril), apparently achieve the same degree of D₂ and D₃ blockade in the temporal lobes while exhibiting substantially less antagonistic activity in the striatum—accounting for their lesser parkinsonian side effects.

Since the introduction, in the 1950s, of the phenothiazine chlorpromazine as an anesthetic agent and its application to schizophrenics as a result of serendipitously discovered antipsychotic activity, a large number of antipsychotic drugs have been marketed for clinical use. No attempt is made here to describe or even list all of them. Some have had only an evanescent popularity, and others have yet to prove their value. Chemically, these compounds form a heterogeneous group; eight of them are of particular clinical importance: (1) the phenothiazines; (2) the thioxanthines; (3) the butyrophenones; (4) the rauwolfia alkaloids; (5) an indole derivative, loxapine (Loxitane), and a unique dihydroindalone, molindone (Moban); (6) a diphenylbutylpiperidine, pimozide (Orap); (7) dibenzodiazepines, typified by clozapine (Clozaril) and olanzapine (Zyprexa); and (8) a benzisoxazole derivative, risperidone (Risperdal). The last four of these drugs were introduced more recently than the others and also have a more limited use. Molindone and loxapine are about as effective as the phenothiazines in the management of schizophrenia, and their side effects are also the same; their main use is in patients who are not responsive to the older drugs or who suffer intolerable side effects from them. The antipsychotic agents in the class of clozapine have attracted great interest, since—as already mentioned—they appear to be relatively free of extrapyramidal side effects. For this reason, they are particularly successful in controlling the confusion and psychosis of parkinsonian patients. The other new class of drugs, of which risperidone is the main example, also has few extrapyramidal side effects and a more rapid onset of action than the traditional antipsychotic medications. Pimozide may be useful in the treatment of haloperidol-refractory cases of Gilles de la Tourette syndrome (page 117); its main danger is its tendency to produce cardiac arrhythmias.

Phenothiazines

This group comprises some of the most widely used tranquilizers, such as the phenothiazines chlorpromazine (Thorazine), promazine (Sparine), triflupromazine (Vesprin), prochlorperazine (Compazine), perphenazine (Trilafon), fluphenazine (Permitil, Prolixin), thioridazine (Mellaril), mesoridazine (Serentil), and trifluoperazine (Stelazine). In addition to their psychotherapeutic effects, these drugs have a number of other actions, so that certain members of this group are used as antiemetics (prochlorperazine) and antihistaminics (promethazine).

The phenothiazines have had their widest application in the treatment of the psychoses (schizophrenia and, to a lesser extent, manic-depressive psychosis). Under the influence of these drugs, many patients who would otherwise be hospitalized are able to live at home and even work productively. In the hospital, the use of these drugs has greatly facilitated the care of hyperactive and combative patients (see [Chap. 57](#) and [Chap. 58](#) for details of the clinical usage of these drugs).

Side effects of the phenothiazines are frequent and often serious. All of them may cause a cholestatic type of jaundice, agranulocytosis, convulsive seizures, orthostatic hypotension, skin sensitivity reactions, mental depression, and, most importantly, immediate or delayed extrapyramidal motor disorders. The neuroleptic malignant syndrome is the most extreme complication and is discussed separately further on. The following types of extrapyramidal symptoms, also discussed on page 1637, have been noted in association with all of the phenothiazines [as well as the butyrophenones and, to a lesser extent, metoclopramide (Reglan) and pimozide, which block dopaminergic receptors]:

1. A parkinsonian syndrome—masked facies, tremor, generalized rigidity, shuffling gait, and slowness of movement. These symptoms may appear after several days of drug therapy but more often after several weeks. Suppression of dopamine in the striatum (similar to the effect of loss of nigral cells) is presumably the basis of the parkinsonian syndrome.
2. Dyskinesia and dystonia, taking the form of involuntary movements of lower facial muscles (mainly around the mouth) and protrusion of the tongue (buccolingual or oral-masticatory syndrome), dysphagia, torticollis and retrocollis, oculogyric crises, and tonic spasms of a limb. These complications usually occur early in the course of administration of the drug, sometimes after the initial dose, in which case they can be improved dramatically by immediate discontinuation of the drug and the intravenous administration of diphenhydramine hydrochloride (Benadryl).
3. An inner restlessness reflected by a persistent shifting of the body and feet and an inability to sit still, such that the patient paces the floor or jiggles the legs constantly (akathisia, see page 118). Of all the phenothiazines, molindone has a special tendency to cause akathisia. This disorder often responds to oral propranolol.
4. A group of *late and persistent complications* of neuroleptic therapy, which may continue after removal of the offending drug, comprises lingual-facial-buccal-cervical dyskinesias, choreoathetotic and dystonic movements of the trunk and limbs, diffuse myoclonus (rare), perioral tremor (“rabbit” syndrome), and dysarthria or anarthria. These movement abnormalities constitute the important group of *tardive dyskinesias*. Snyder has postulated that the movements are due to hypersensitivity of dopamine receptors in the basal ganglia, secondary to prolonged blockade of the receptors by antipsychotic medication. Baldessarini estimates that as many as 40 percent of patients receiving long-term antipsychotic medication develop tardive dyskinesia of some degree. A pathology has never been ascertained.
5. The neuroleptic malignant syndrome, which is discussed separately below.

Butyrophenones Haloperidol (Haldol) is the only member of this group approved for use as an antipsychotic in the United States. It has much the same therapeutic effects as the phenothiazines in the management of the acute psychoses. It also has the same side effects as the phenothiazines but has little or no adrenergic blocking action. It is an effective substitute for the phenothiazines in patients who are intolerant of the latter drugs, particularly of their autonomic effects. It is also one of the drugs of choice in treating Gilles de la Tourette syndrome (the other being pimozide) and the movement disorder of Huntington chorea.

Treatment of Neuroleptic Side Effects As indicated above, acute dystonic spasms usually respond to diphen-hydramine (Benadryl). The purely parkinsonian syndrome usually improves as well, but the tardive dyskinesias may persist for months or years and may be permanent. Administration of antiparkinsonian drugs of the anticholinergic type (trihexyphenidyl, procyclidine, and benztropine) may hasten recovery from some of the symptoms. Oral, lingual, and laryngeal dyskinesias are affected relatively little by any antiparkinsonian drugs. Amantadine (Symmetrel) in doses of 50 to 100 mg tid has been useful in some cases of postphenothiazine dyskinesia. Many other drugs have been tried in the treatment of tardive dyskinesia, with uncertain results. No treatment has been uniformly successful in the present authors' experience. Nevertheless, we have noted a tendency for most of the obstinate forms of tardive dyskinesia to subside slowly even after several years of unsuccessful therapy. The use of low doses of antipsychotic drugs and frequent drug holidays, especially in the more susceptible older patients, may help to prevent the development of tardive dyskinesia.

Neuroleptic Malignant Syndrome This is the most dreaded complication of phenothiazine and haloperidol use; its incidence has been calculated to be 0.2 percent of all patients receiving neuroleptics ([Caroff and Mann](#)), and its seriousness is underscored by a mortality rate of 15 to 30 percent if not recognized and treated promptly. It may occur days, weeks, or months after neuroleptic treatment is begun. The syndrome consists of catatonic rigidity, stupor, unstable blood pressure, variable hyperthermia, diaphoresis and other signs of autonomic dysfunction, high serum creatine kinase (CK) values (up to 60,000 units), and, in fatal cases, renal failure due to myoglobinuria. The syndrome was first observed in patients being treated with haloperidol, and since then other neuroleptic drugs have been incriminated, particularly the highly potent thioxanthine derivative thiothixine and the phenothiazines—chlorpromazine, fluphenazine, and thioridazine—but also, on rare occasions, the less potent drugs that are used to control nausea, such as promethazine. It has recently become evident that the newer antipsychotic drugs, and specifically olanzapine, are also capable of inducing the syndrome. All of these drugs are thought to act through blockade of dopamine receptors in the basal ganglia and hypothalamus.

The neuroleptic malignant syndrome bears a close relationship to *malignant hyperthermia*, not only in its clinical aspects but also in its response to bromocriptine and dantrolene. Malignant hyperthermia is an inherited disorder that, in susceptible individuals, is triggered by inhalation anesthetics and skeletal muscle relaxants (page 1563). This disorder was described before the introduction of neuroleptic drugs and has recently been related to a mutation of the ryanodine receptor gene on chromosome 19q. A genetic factor is also suspected to underlie the neuroleptic malignant syndrome, possibly provoked by fatigue and dehydration.

If treatment is started early, when consciousness is first altered and the temperature is rising, bromocriptine in oral doses of 5 mg tid (up to 20 mg tid) will terminate

the condition in a few hours. Once oral medication can no longer be taken, dantrolene, 0.25 to 3.0 mg intravenously may be lifesaving. Once coma has supervened, shock and anuria may prove fatal or leave the patient in a vegetative state. The rigors during high fever may cause muscle damage and myoglobinuria, and the circulatory collapse may lead to hypoxic-ischemic brain injury.

Meningitis, heat stroke, lithium intoxication, and acute dystonic reactions figure in the differential diagnosis. Of course, neuroleptic medication must be discontinued as soon as any of the severe extrapyramidal reactions are recognized, and it is felt that the offending neuroleptic should not be used in the future; but the risk of using another class of antipsychotic agent has not been fully addressed.

It hardly needs to be pointed out that the antipsychotic drugs have been much overused. This would be suspected just from the frequency with which they are being prescribed. These powerful medications have specific indications, noted above and in [Chap. 56](#), [Chap. 57](#), and [Chap. 58](#), and the physician should be certain of the diagnosis before using them. The fact that the neuroleptic drugs can produce tardive dyskinesia in nonpsychotic patients is reason enough not to use them for nervousness, apprehension, anxiety, mild depression, and the many normal psychologic reactions to trying environmental circumstances. These drugs are not curative but only suppress or partially alleviate symptoms, and they should not serve as a substitute for, or divert the physician from, the use of other measures for the relief of abnormal mental states.

ANTIDEPRESSANTS

Four classes of drugs—the monoamine oxidase (MAO) inhibitors, the tricyclic compounds, the serotonergic drugs, and lithium—are particularly useful in the treatment of depressive illnesses. The adjective *antidepressant* refers to their therapeutic effect and is employed here in deference to common clinical practice. *Antidepressive* or *antidepress* drugs would be preferable, since the term *depressant* still has a pharmacologic connotation that does not necessarily equate with the therapeutic effect. For example, barbiturates and chloral hydrate are depressants in the pharmacologic sense and mood elevators or antidepressants in the clinical sense.

Monoamine Oxidase Inhibitors

The observation that iproniazid, an inhibitor of monoamine oxidase (MAO), had a mood-elevating effect in tuberculous patients initiated a great deal of interest in compounds of this type and led quickly to their exploitation in the treatment of depression. Iproniazid proved exceedingly toxic to the liver and was soon taken off the market, as were several subsequently developed MAO inhibitors; but other drugs in this class, much better tolerated, are still available. These include isocarboxazid (Marplan), phenelzine (Nardil), and tranylcypromine (Parnate), the latter two being the more frequently used. Tranylcypromine, which bears a close chemical resemblance to dextroamphetamine, may produce unwanted stimulation, but the most common adverse effect of all the MAO inhibitors is postural hypotension. Also, interactions with a wide array of other drugs and ingested substances may produce severe hypertension.

Monoamine oxidase is located on the outer surface of the mitochondria in neurons and is utilized in the catabolism of catecholamines ([Coyle](#)). In the gut and liver, this enzyme normally serves to deaminate phenethylamine, tyramine, and tryptamine—the products of protein catabolism. Inhibition of MAO allows these dietary amines, which have an amphetamine-like action, to enter the systemic circulation in increased quantities, thus releasing norepinephrine from sympathetic nerve endings and increasing heart rate and blood pressure. Probably more relevant to their action as antidepressants, the MAO inhibitors also have in common the ability to block the intraneuronal oxidative deamination of naturally occurring amines (norepinephrine, epinephrine, and serotonin), and it has been suggested that the accumulation of these substances is responsible for the antidepressant effect. However, many enzymes other than monoamine oxidase are inhibited by MAO inhibitors, and the latter drugs have numerous actions unrelated to enzyme inhibition. Furthermore, many agents with antidepressant effects like those of the MAO inhibitors do not inhibit MAO. One cannot assume that the therapeutic effect of these drugs has a direct relation to the property of MAO inhibition in the brain.

The MAO inhibitors must be dispensed with great caution and constant awareness of their potentially serious side effects. They may at times cause excitement, restlessness, agitation, insomnia, and anxiety, occasionally with the usual dose but more often with an overdose. Mania and convulsions may occur (especially in epileptic patients). Other side effects are muscle twitching and involuntary movements, urinary retention, skin rashes, tachycardia, jaundice, visual impairment, enhancement of glaucoma, impotence, sweating, muscle spasms, paresthesias, and a serious degree of orthostatic hypotension.

Patients taking MAO inhibitors must be warned against the use of phenothiazines, CNS stimulants, tricyclic and serotonergic antidepressants (see below), and also sympathomimetic amines and tyramine; the combination of an MAO inhibitor and any of these drugs or amines may induce severe hypertension, atrial and ventricular arrhythmia, pulmonary edema, stroke, and even death. Sympathomimetic amines are contained in some commonly used cold remedies, nasal sprays, nose drops, and certain foods—aged cheese, beer, red wine, pickled herring, sardines, sausages, and preserved meat or fish. Exaggerated responses to the usual dose of meperidine (Demerol) and other narcotic drugs have also been observed; respiratory function may be depressed to a serious degree, and hyperpyrexia, agitation, and pronounced hypotension may occur as well, sometimes with fatal issue. Unpredictable side effects may also accompany the simultaneous administration of barbiturates and MAO inhibitors. The abrupt occurrence of severe occipital headache, nausea, vomiting, pupillary dilation, or visual blurring should suggest a hypertensive crisis; treatment is with intravenous phentolamine 5 mg, nitroprusside, or a calcium channel blocker administered slowly to prevent hypotension. Overdosage presents with coma, for which there is no treatment other than supportive care.

The therapeutic use of MAO inhibitors is discussed further in [Chap. 56](#) and [Chap. 57](#).

Tricyclic Antidepressants

Soon after the first successes with MAO inhibitors, a new class of tricyclic compounds appeared. The first was imipramine (Tofranil), soon followed by amitriptyline (Elavil) and then by desipramine (Norpramin) and nortriptyline (Pamelor). Another important dibenzazepine derivative is carbamazepine (Tegretol), which is widely used in the control of seizures but has also found a role in the treatment of lancinating neuropathic and myelopathic pain and possibly of depression and mood instability. Subsequently, a number of additional antidepressant drugs were introduced. Included are variants of the conventional tricyclic drugs (amoxapine, protriptyline, trimipramine, doxepin), tetracyclics (maprotiline), bicyclics (zimeldine), and others (trazodone, bupropion). A full account of these drugs, which cannot be attempted here, will be found in the monographs of Hollister and of Pirodsky and Cohn. The newer drugs seem to be safer than the older ones when taken in overdose, but whether they have a clear therapeutic advantage in depression has not been established.

The mode of action of these agents is not fully understood, but there is evidence that they block the reuptake of amine neurotransmitters, both norepinephrine and serotonin. Blocking this amine pump mechanism (called the presynaptic plasma transporter), which ordinarily terminates synaptic transmission, permits the persistence of neurotransmitter substances in the synaptic cleft and supports the hypothesis that endogenous depression is due to a deficiency of noradrenergic or serotonergic transmission.

The tricyclic antidepressants and the serotonergic drugs discussed in the next section, are presently the most effective drugs for the treatment of patients with depressive illnesses, the former being particularly useful for those with anergic depressions associated with hyposomnia, early morning awakening, and decreased appetite and libido. The side effects of the tricyclic drugs are far less frequent and serious than those of the MAO inhibitors.

The tricyclic (dibenzazepine) compounds are potent anticholinergic agents, which accounts for their most prominent and serious side effects—orthostatic hypotension and urinary bladder weakness. They may also produce CNS excitement—leading to insomnia, agitation, and restlessness—but usually these effects are readily controlled by small doses of phenothiazines or benzodiazepines given concurrently or in the evenings. Occasionally they may cause ataxia and blood dyscrasias. As indicated above, the tricyclic drugs should not be given with an MAO inhibitor; serious reactions have allegedly occurred when small doses of imipramine were given to patients who had discontinued the MAO inhibitor 1 week previously. Finally, it must be repeated that both the MAO inhibitors and the tricyclic antidepressants are extremely dangerous drugs when taken in excess.

Tricyclic compounds are a frequent cause of accidental poisoning and a favorite suicidal instrument of depressed patients. It is common for the intoxicated patient to have taken several drugs, in which case chemical analyses of the blood and urine are particularly helpful in determining the drugs involved and in sorting out therapeutic and toxic concentrations. Mortality from overdose is due to cardiac disturbances, particularly tachyarrhythmias and impaired conduction. Treatment consists of gastric aspiration and instillation of activated charcoal and the addition of physostigmine to reverse serious arrhythmias; its short duration of action requires that frequent doses be given. Dialysis is of no value because of the low plasma concentrations of the drug.

Serotonin Reuptake Inhibitors and Related Drugs

The selective serotonin reuptake inhibitors (SSRI) constitute a newer class of antidepressants; paroxetine (Paxil), fluoxetine (Prozac), and sertraline (Zoloft) are the ones most often used, but others are being developed at a rapid pace. They act presumably by inhibiting the reuptake of serotonin and to a slightly lesser extent of norepinephrine, somewhat like the effect of a tricyclic. This results in a potentiation of the actions of these neurotransmitters. Because they do not bind as avidly as tricyclic drugs to the muscarinic and adrenergic receptors in the brain, they produce fewer side effects, but some patients complain of anxiety or insomnia when they are first introduced. *As with the tricyclic agents, the concomitant administration of MAO inhibitors is hazardous.* There should be a period of at least 1 week between the administration of these two classes of drugs to allow for the washout of the last agent used. The symptoms of a “serotonin syndrome” that results from excessive intake or from the concurrent use of MAO inhibitors include confusion, restlessness, myoclonus, shivering, and diaphoresis, as summarized by Sternbach.

The SSRI drugs are well tolerated, may be effective in a shorter time than the tricyclic agents, and are justifiably very popular at the moment, but their long-term therapeutic usefulness in comparison with their predecessors remains to be determined (see review of [Richelson](#)). Fluoxetine has also been used with benefit in a group of autistic children (page 1100). Several related drugs such as venlafaxine (Effexor), nefazodone (Serzone), and citalopram (Celexa) have novel structures that are not analogous to those of the other categories of antidepressants. They are believed to act similarly to the SSRI class by inhibiting the reuptake of serotonin and norepinephrine. These newer drugs share most of the side effects of the SSRI drugs, including the danger of concomitant MAO inhibitor administration.

Lithium

The discovery of the therapeutic effects of lithium salts in mania has led to its widespread use in the treatment of manic-depressive disease (bipolar disorder). The drug has proved relatively safe and blood levels are easily monitored. Its value is much more certain in treatment of the manic phase of bipolar disorder and prevention of recurrences of cyclic mood shifts than it is in treatment of anxiety and depression. Guidelines for the clinical use of lithium are given in [Chap. 57](#). Its mechanism of action is unclear, but there is experimental evidence that lithium blocks the stimulus-induced release of norepinephrine and enhances the reuptake of this amine—the opposite, in a sense, of what occurs with the other classes of antidepressants.

With blood levels of lithium in the upper therapeutic range, it is not uncommon to observe a fast-frequency action tremor or asterixis, together with nausea, loose stools, fatigue, polydipsia, and polyuria. These symptoms usually subside with time. Above a level of 1.5 to 2 meq/L, particularly in patients with impaired renal function or in those taking a thiazide diuretic, serious intoxication becomes manifest—clouding of consciousness, confusion, delirium, dizziness, nystagmus, ataxia, stammering, diffuse myoclonic twitching, and nephrogenic diabetes insipidus. Vertical (downbeating) nystagmus and opsoclonus may also be prominent. This clinical state, associated with sharp waves in the EEG, may mimic Creutzfeldt-Jakob disease, but there should be no problem in diagnosis if the setting of the illness and the administration of lithium are known. At a blood lithium concentration of 3.5 meq/L, these symptoms are replaced by stupor and coma, sometimes with convulsions, and may prove fatal.

Discontinuing lithium in the intoxicated patient, which is the initial step in therapy, does not result in immediate disappearance of toxic symptoms. This may be delayed by a week or two, and the diabetes insipidus may persist even longer. Fluids, sodium chloride, aminophylline, and acetazolamide promote the excretion of lithium. Lithium coma may require hemodialysis, which has proved to be the most rapid means of reducing the blood lithium concentration.

STIMULANTS

Drugs that act primarily as CNS stimulants have a relatively limited therapeutic use but assume clinical importance for other reasons. Some members of this group, e.g., the amphetamines, are much abused, and others are not infrequent causes of poisoning.

Amphetamine (Benzedrine, Adderall) This drug and dextroamphetamine, its D-isomer, are powerful analeptics (CNS stimulants) and in addition have significant hypertensive, respiratory-stimulant, and appetite-depressant effects. They are useful in the management of narcolepsy but have been much more widely and indiscriminately used for the control of obesity, the abolition of fatigue, and the treatment of hyperactivity in children. Undoubtedly, they are able to reverse fatigue, postpone the need for sleep, and elevate mood, but these effects are not entirely predictable, and the user must pay for the period of wakefulness with even greater fatigue and often with depression. The intravenous use of a high dose of amphetamine produces an immediate feeling of ecstasy, the “flash.”

Because of the popularity of the amphetamines and the ease with which they can be procured, instances of acute and chronic intoxication are observed frequently. The toxic signs are essentially an exaggeration of the analeptic effects—restlessness, excessive speech and motor activity, tremor, and insomnia. Severe intoxication may give rise to hallucinations, delusions, and changes in affect and thought processes—a state that may be indistinguishable from paranoid schizophrenia. Amphetamine vasculitis and intracerebral and subarachnoid hemorrhage are well-recognized but rare complications of chronic intoxication ([Harrington](#) et al), and they may occur after acute use as well. Similar cerebrovascular complications occur with sympathomimetic agents contained in over-the-counter cold medications and in dieting aids; phenylpropanolamine has been implicated most often, but ephedrine and similar agents rarely have the same effects and induce a vasculopathy. The pathogenesis of the vascular lesion is unknown (both vasospasm and arteritis have been reported), and the same state occurs with cocaine, as described below.

Chronic use of amphetamines can lead to a high degree of tolerance and psychologic dependence. Withdrawal of the drug after sustained oral or intravenous use is regularly followed by a period of prolonged sleep (a disproportionate amount of which is REM sleep), from which the patient awakens with a ravenous appetite, muscle pains, and feelings of profound fatigue and depression. Treatment consists of discontinuing the use of amphetamine and administering antipsychotic drugs. Nitrites may be useful if the blood pressure is markedly elevated.

Methylphenidate (Ritalin) This drug has much the same type of action as dextroamphetamine and is useful in the treatment of narcolepsy. Paradoxically, like amphetamine, it is useful in the management of attention- deficit hyperactivity disorder in children (see page 629).

HALLUCINOGENS

Included in this category is a heterogeneous group of drugs, the primary effect of which is to alter perception, mood, and thinking out of proportion to other aspects of cognitive function and consciousness. This group of drugs comprises *cocaine*, *lysergic acid derivatives* [e.g., lysergic acid diethylamide (LSD)], *phenylethylamine derivatives* (mescaline or peyote), *psilocybin*, *certain indolic derivatives*, *cannabis* (marijuana), *phencyclidine* (PCP), and a number of less important compounds. They are also referred to as psychoactive and psychotomimetic drugs and as hallucinogens and psychedelics—but none of these names is entirely suitable. The problems raised by the nontherapeutic use of these drugs, which has declined somewhat but is still of serious proportions, have been reviewed by Nicholi and by Peroutka, and by Verebey and their associates.

Cocaine

The conventional use of cocaine as a local anesthetic has for many years been overshadowed by its illicit and widespread use as a stimulant and mood elevator. Originally, cocaine was sold as a white, lactose-adulterated powder that was usually administered intranasally (“snorted”); less often, it was smoked or injected intravenously or intramuscularly. Since 1985 there has been an alarming escalation in the use of cocaine, mainly because a relatively pure and inexpensive form of the free alkaloid base (“crack”) became readily available at that time. This form of cocaine is heat-stable and therefore suitable for smoking. According to the National Household Survey on Drug Abuse, there were, in 1998, an estimated 600,000 frequent cocaine users in the United States. (Frequent use was arbitrarily defined as use on 51 or more days during the preceding year.) The number of occasional users (less than 12 days in the preceding year) was 2.4 million. These figures are subject to significant underreporting.

A sense of well-being, euphoria, loquacity, and restlessness are the familiar effects. Pharmacologically, cocaine is thought to act like the tricyclic antidepressants; i.e., it blocks the presynaptic reuptake of biogenic amines, thus producing vasoconstriction, hypertension, and tachycardia and predisposing to generalized tremor, myoclonus, seizures, and psychotic behavior. These actions as well as its immediate mood-elevating and euphoric effects are much the same as those of dextroamphetamine (see above). The cocaine abuser readily develops psychologic dependence or habituation, i.e., an inability to abstain from frequent compulsive use (“craving”). The manifestations of physical dependence are more subtle and difficult to recognize. Nevertheless, abstinence from cocaine following a period of chronic abuse is regularly attended by insomnia, restlessness, anorexia, depression, hyperprolactinemia, and signs of dopaminergic hypersensitivity—a symptom

complex that constitutes an identifiable withdrawal syndrome.

With the increasingly widespread use of cocaine, a variety of new complications continues to emerge. The symptoms of severe intoxication (overdose), noted above, may lead to coma and death and require emergency treatment in an intensive care unit, along the lines indicated for the management of barbiturate coma. Seizures often occur in this setting and are treated more effectively with benzodiazepines than with standard anticonvulsant drugs. Spontaneous subarachnoid or intracerebral hemorrhage and cerebral infarction have rarely followed the intranasal use and smoking of cocaine ([Levine](#) et al). These complications are presumably the result of vasospasm induced by the sympathomimetic actions of cocaine. Cocaine and amphetamines also, on occasion, produce a state of generalized vasospasm leading to multiple cortical infarctions and posterior white matter changes that are evident on imaging studies, not unlike those seen with hypertensive encephalopathy (page 903). Several cases of a pathologically verified vasculitis and instances of “beading” of cerebral vessels on the arteriogram have been reported. We have seen several instances of vasospasm but have no experience with the vasculitis; however, it would seem that two different types of vasculopathy can result from cocaine and amphetamine use. Roth and colleagues have described 39 patients who developed acute rhabdomyolysis after cocaine use; 13 of these had acute renal failure, severe liver dysfunction, and disseminated intravascular coagulation and 6 of them died. Some reports indicate that cocaine use during pregnancy may cause fetal damage, abortion, or persistent signs of toxicity in the newborn infant.

Anxiety, paranoia, and other manifestations of psychosis may develop within several hours of cocaine use. These complications are best treated with haloperidol.

Marijuana

During the past three decades the prevalence of marijuana use has declined by about half, but it is still the most commonly used illicit drug in the United States. Its effects, when taken by inhaling the smoke from cigarettes, are prompt in onset and evanescent. With low doses, the symptoms are like those of mild alcohol intoxication (drowsiness, euphoria, dulling of the senses, and perceptual distortions). With increasing amounts, the effects are similar to those of LSD, mescaline, and psilocybin (see below); they may be quite disabling for many hours. With even larger doses, severe depression and stupor may occur, but death is rare (for a full account, see [Hollister, 1988](#)). No damage to the nervous system has been found after chronic use.

Reverse tolerance to marijuana (i.e., increasing sensitization) may be observed initially, but on continued use, tolerance to the euphoriant effects develops. In one of the few experimental studies of chronic marijuana use, the subjects reported feeling “jittery” during the first 24 h after abrupt cessation of smoking marijuana, although no objective withdrawal signs could be detected.

The mild antiemetic and antinauseant effects of marijuana coupled with euphoria have led to its use as an agent to ameliorate the effects of cancer chemotherapies, and this purported therapeutic effect is the mainstay of the movement for its legalization.

Mescaline, LSD, and Psilocybin

These drugs produce much the same clinical effects if given in comparable amounts. The perceptual changes are the most dramatic: the user describes vivid visual hallucinations, alterations in the shape and color of objects, unusual dreams, and feelings of depersonalization. An increase in auditory acuity has been described, but auditory hallucinations are rare. Cognitive functions are difficult to assess because of inattention, drowsiness, and inability to co-operate in mental testing. The somatic symptoms consist of dizziness, nausea, paresthesias, and blurring of vision. Sympathomimetic effects—pupillary dilation, piloerection, hyperthermia, and tachycardia—are prominent, and the user may also show hyperreflexia, incoordination of the limbs, and ataxia.

Tolerance to LSD, mescaline, and psilocybin develops rapidly, even on a once-daily dosage. Furthermore, subjects tolerant to any one of these three drugs are cross-tolerant to the other two. Tolerance is lost rapidly when the drugs are discontinued abruptly, but no characteristic signs of physical dependence (abstinence syndrome) ensue. In this sense, addiction does not develop, although users may become dependent upon the drugs for emotional support (psychologic dependence or habituation).

Although LSD has no therapeutic value and the use of marijuana is governed by the federal narcotic laws, these drugs are widely used. They are taken by narcotic addicts as a temporary substitute for more potent drugs; by “drugheads” (i.e., individuals who use any agent that alters consciousness); and by many troubled, unhappy college and high school students for social conformity or for reasons that even they cannot ascertain. The use of these drugs is attended by a number of serious adverse reactions taking the form of acute panic attacks, long-lasting psychotic states resembling paranoid schizophrenia, and flashbacks (spontaneous recurrences of the original LSD experience, sometimes precipitated by smoking marijuana and accompanied by panic attacks). Serious physical injury may follow upon impairment of the user's critical faculties. Whether prolonged usage leads to permanent damage to the nervous system is not certain; there are some data to suggest that this may happen, but there is little doubt that the mental state of some psychologically predisposed individuals is permanently altered. The reports claiming that LSD may cause chromosomal damage remain to be validated. Numerous claims have been made that LSD and related drugs are effective in the treatment of mental disease and a wide variety of social ills and that they have the capacity to increase one's intellectual performance, creativity, and self-understanding. To date there have been no acceptable studies that validate any of these claims.

Phencyclidine (“Angel Dust” and “Ecstasy”)

During the early 1970s, the abuse of phencyclidine (PCP) and its many analogues was a significant problem. The popularity of these drugs has dropped sharply, but some illicit use continues because they are relatively cheap, easily available, and quite powerful. Phencyclidine is taken illicitly as a granular powder, frequently mixed with other drugs, and is smoked or snorted. It is usually classified as a hallucinogen, although it also has stimulant and depressant properties. The effects of intoxication are like those of LSD and other hallucinogens and resemble those of an acute schizophrenic episode, which may last several days to a week or more. After the ingestion of a large amount (10 mg or more) of phencyclidine, it is present in the blood and urine for only a few hours. Its manufacture as a veterinary anesthetic was stopped in 1979.

Toxicity from the illicit use of “ecstasy” (MDMA) during all-night dance parties (raves) has recently increased as a result of its ill-founded reputation for safety. It appears to cause a release of both serotonin and dopamine in the brain and produces an elated state similar to the effects of cocaine. Seizures, cerebral hemorrhages, and psychosis have been reported in previously healthy individuals (Vereby et al).

A discussion of the legal implications of the illicit use of the aforementioned drugs and their social impact is beyond the scope of this chapter but can be found in the appended references.

DISORDERS DUE TO BACTERIAL TOXINS

The most important diseases in this category are tetanus, botulism, and diphtheria. Each is caused by an extraordinarily powerful bacterial toxin that acts primarily upon the nervous system.

Tetanus

The cause of this disease is the anaerobic, spore-forming rod *Clostridium tetani*. The organisms are found in the feces of some humans and many animals, particularly horses, whence they readily contaminate the soil. The spores may remain dormant for many months or years, but when they are introduced into a wound, especially if a foreign body or suppurative bacteria are present, they are converted into their vegetative forms, which produce the exotoxin tetanospasmin. In developing countries, tetanus is still a common disease, particularly in newborns, in whom the spores are introduced via the umbilical cord (*tetanus neonatorum*). In the United States, the incidence rate of tetanus is about one per million per year. Injection of contaminated heroin is a significant cause. About two-thirds of all injuries leading to tetanus occur from deep scratches and puncture wounds in the home and about 20 percent in gardens and on farms.

Since 1903, when Morax and Marie proposed their theory of centripetal migration of the tetanus toxin, it has been taught that spread to the nervous system occurs via the peripheral nerves, the toxin ascending in the axis cylinders or the perineural sheaths. Modern studies, utilizing fluorescein-labeled tetanus antitoxin, have disclosed that the toxin is also widely disseminated via blood or lymphatics, probably accounting for the generalized form of the disease. However, in local tetanus, the likely mode of spread to the CNS is by retrograde axonal transport.

Mode of Action of Tetanus Toxin Like botulinum toxin, the tetanus toxin is a zinc-dependent protease. It blocks neurotransmitter release by cleaving surface proteins of the synaptic vesicles, thus preventing the normal exocytosis of neurotransmitter. The toxin interferes with the function of the reflex arc by the blockade of inhibitory transmitters, mainly GABA, at presynaptic sites in the spinal cord and brainstem. Elicitation of the jaw jerk, for example, is normally followed by the abrupt suppression of motor neuron activity, manifested in the electromyogram (EMG) as a “silent period” (see further on). In the patient with tetanus, there is a failure of this inhibitory mechanism, with a resulting increase in activation of the neurons that innervate the masseter muscles (*trismus* or lockjaw). Of all neuromuscular systems, the masseter innervation seems to be the most sensitive to the toxin. Not only do afferent stimuli produce an exaggerated effect, but they also abolish reciprocal innervation; both agonists and antagonists contract, giving rise to the characteristic muscular spasm. In addition to its generalized effects on the motor neurons of the spinal cord and brainstem, there is evidence that the toxin acts directly on skeletal muscle at the point where the axon forms the end plate (accounting perhaps for localized tetanus) and also upon the cerebral cortex and the sympathetic nervous system, in the hypothalamus.

The incubation period varies greatly, from a day or two to a month or even longer. Long incubation periods are associated with mild and localized types of the disease.

Clinical Features There are several clinical types of tetanus, usually designated as local, cephalic, and generalized.

Generalized Tetanus This is the most common form. It may begin as local tetanus that becomes generalized after a few days, or it may be diffuse from the beginning. Trismus is frequently the first manifestation. In some cases this is preceded by a feeling of stiffness in the jaw or neck, slight fever, and other general symptoms of infection. The localized muscle stiffness and spasms spread quickly to other bulbar muscles as well as those of the neck, trunk, and limbs. A state of unremitting rigidity develops in all the involved muscles: the abdomen is board-like, the legs are rigidly extended, and the lips are pursed or retracted (*risus sardonicus*); the eyes are partially closed by contraction of the orbicularis oculi or the eyebrows are elevated by spasm of the frontalis. Superimposed on this persistent state of enhanced muscle activity are paroxysms of tonic contraction or spasm of muscles (tetanic seizures or convulsions), which occur spontaneously or in response to the slightest external stimulus. They are agonizingly painful. Consciousness is not lost during these paroxysms. The tonic contraction of groups of muscles results in opisthotonos or in forward flexion of the trunk, flexion and adduction of the arms, clenching of the fists, and extension of the legs. Spasms of the pharyngeal, laryngeal, or respiratory muscles carry the constant threat of apnea or suffocation. Fever and pneumonia are common complications. Large swings in blood pressure and pulse as well as profuse diaphoresis are typical, mainly in response to the intense muscular contractions but also related to the action of the toxin on the CNS. Death is usually attributable to asphyxia from laryngospasm, to heart failure, or to shock, the latter resulting from the action of the toxin on the hypothalamus and sympathetic nervous system.

Generalized spasms and rigidity of trunk and limbs developing in a neonate a few days after birth should always suggest the diagnosis of tetanus. This form of tetanus occurs when there has been inadequate sterile treatment of the umbilical cord stump in a neonate born to an unimmunized mother.

Local Tetanus This is the most benign form. The initial symptoms are stiffness, tightness, and pain in the muscles in the neighborhood of a wound, followed by twitchings and brief spasms of the affected muscles. Local tetanus occurs most often in relation to a wound of the hand or forearm, rarely in the abdominal or paravertebral muscles. Gradually, some degree of continuous involuntary spasm becomes evident. This is referred to as *rigidity*, *hypertonic contractions*, or *tetanic spasticity*, terms that denote the sustained tautness of the affected muscles and resistance of the part to passive movement. Superimposed on this background of more or less continuous motor activity are brief, intense spasms, lasting from a few seconds to minutes and occurring “spontaneously” or in response to all variety of stimulation ([Struppler](#) et al). Early in the course of the illness there may be periods when the affected muscles are palpably soft and appear to be relaxed. A useful diagnostic maneuver at this stage is to have the patient perform some repetitive voluntary movements, such as opening and closing the hand, in response to which there occurs a gradual increase in the tonic contraction and spasms of the affected muscles, followed by spread to neighboring muscle groups (recruitment spasm). The phenomenon resembles paradoxical myotonia (page 1559). Even with mild localized tetanus there may be a slight trismus, a useful diagnostic sign.

Symptoms may persist in localized form for several weeks or months. Gradually the spasms become less frequent and more difficult to evoke, and they finally disappear without residue. Complete recovery is to be expected, since there are no pathologic changes in muscles, nerves, spinal cord, or brain, even in the most severe generalized forms of tetanus.

Cephalic Tetanus This form of tetanus follows wounds of the face and head. The incubation period is short, 1 or 2 days as a rule. The affected muscles (most often facial) are weak or paralyzed. Nevertheless, during accessions of tetanic spasm, the palsied muscles are seen to contract. Apparently the disturbance in the facial motoneurons is sufficient to prevent voluntary movement but insufficient to prevent the strong reflex impulses that elicit facial spasm. The spasms may involve the tongue and throat, with persistent dysarthria, dysphonia, and dysphagia. Ophthalmoparesis is known to occur but is difficult to verify because of severe blepharospasm. In a strict sense these cephalic forms of tetanus are examples of local tetanus that frequently becomes generalized. Many cases prove fatal.

Diagnosis This is made from the clinical features and a history of preceding injury. The latter is sometimes disclosed only after careful questioning, the injury having been trivial and forgotten. The organisms may or may not be recovered from the wound by the time the patient receives medical attention; other laboratory tests, apart from the EMG, are of little value. Serum CK may be moderately elevated if the rigidity is generalized. The EMG recorded from muscles in spasm shows continuous discharges of normal motor units like those recorded from a forceful voluntary muscle contraction. Most characteristic of tetanus, as mentioned earlier, is a loss of the silent period that occurs 50 to 100 ms after reflex contraction. This pause, normally effected by the recurrent inhibition of Renshaw cells, is blocked by tetanus toxin. In generalized tetanus the loss of the silent period can almost always be demonstrated in the masseter, and it is found in a muscle affected by local tetanus. Interestingly, the silent period is preserved in the stiff man syndrome (page 1569). Tetany due to hypocalcemia, the spasms of strychnine poisoning or black widow spider bite, trismus due to painful conditions in and around the jaw, the dysphagia of rabies, hysterical spasms, rigidity and dystonic spasms caused by neuroleptic drugs, and the spasms of the stiff man syndrome all resemble the spasms of tetanus but should not be difficult to distinguish when all aspects of these disorders are considered.

The death rate from tetanus is about 50 percent overall; it is highest in newborns, heroin addicts, and patients with the cephalic form of the disease. The patient usually recovers if there are no severe generalized muscle spasms during the course of the illness or if the spasms remain localized.

Treatment This must be directed along several lines. At the outset, a single dose of antitoxin (3000 to 6000 units of tetanus immune human globulin) should be given and a 10-day course of penicillin (1.2 million units of procaine penicillin daily), metronidazole (500 mg every 6 h intravenously or 400 mg rectally), or tetracycline (2 g daily) instituted. These drugs are effective against the vegetative forms of *C. tetani*. Immediate surgical treatment of the wound (excision or debridement) is imperative, and the tissue around the wound should be infiltrated with antitoxin.

Survival depends upon expert and constant nursing in an intensive care unit and may be necessary for weeks. Tracheostomy is a requisite in all patients with recurrent generalized tonic spasms and should not be delayed until apnea or cyanosis has occurred. The patient must be kept as quiet as possible to avoid stimulus-induced spasms. This requires a darkened, quiet room and the judicious use of sedation. The benzodiazepines are the most useful drugs; diazepam 120 mg/day or more can be given in frequent divided doses if ventilatory support is available, or midazolam can be given in a continuous intravenous infusion. Short-acting barbiturates (secobarbital or pentobarbital) and chlorpromazine may also be useful, as is morphine. Intrathecal baclofen and continuous atropine infusions have been used with success in severe cases, and intramuscular injections of botulinus toxin may be used for trismus and local spasm. The aim of therapy is to suppress muscle spasms and to keep the patient drowsy but arousable. All treatments and manipulations should be kept to a minimum; they should be carefully planned and coordinated, and the patient should be sedated beforehand.

Failure of these measures to control the tetanic paroxysms demands that intravenous administration of neuromuscular blocking agents such as pancuronium or vecuronium be used to abolish all muscle activity; appropriate sedative medication is instituted for as long as necessary, breathing being maintained entirely by a positive-pressure respirator. Many units favor the use of neuromuscular paralytic drugs in all but the mildest cases. Further details concerning treatment in the intensive care unit can be found in the recent review by Farrar et al.

All persons should be immunized against tetanus and receive a booster dose of toxoid every 10 years—a practice that is frequently neglected in the elderly. Injuries that carry a threat of tetanus should be treated by an injection of toxoid if the patient has not received a booster injection in the preceding year, and a second dose of toxoid should be given 6 weeks later. If the injured person has not received a booster injection since the original immunization, he or she should receive an injection of both toxoid and human antitoxin; the same applies to the injured person who has never been immunized. An attack of tetanus does not confer permanent immunity, and all persons who recover should be actively immunized.

Diphtheria

Diphtheria, an acute infectious disease caused by *Corynebacterium diphtheriae*, is now quite rare in the United States and western Europe. The faucial-pharyngeal form of the disease, which is the most common clinical type, is characterized by the formation of an inflammatory exudate of the throat and trachea; at this site, the bacteria elaborate an exotoxin, which affects the heart and nervous system in about 20 percent of cases.

The involvement of the nervous system follows a predictable pattern ([Fisher and Adams](#)). It begins locally, with *palatal paralysis* (nasal voice, regurgitation, and dysphagia) between the fifth and twelfth days of illness. At this time or shortly afterward, other cranial nerves (trigeminal, facial, vagus, and hypoglossal) may also be affected. *Ciliary paralysis* with loss of accommodation and blurring of vision appears usually in the second or third week. Very rarely the extraocular muscles are involved. The cranial nerve signs may clear without further involvement of the nervous system, or a sensorimotor polyneuropathy may develop between the fifth and eighth weeks of the disease. The latter varies in severity from a mild, predominantly distal affection of the limbs to a rapidly evolving, ascending paralysis, like that of the Guillain-Barré syndrome; CSF findings are similar as well (acellular fluid with elevated protein). The neuropathic symptoms progress for a week or two, and if the patient does not succumb to respiratory paralysis or cardiac failure (cardiomyopathy), these conditions stabilize and then improve slowly and more or less completely.

The early oropharyngeal symptoms, the unique ciliary paralysis, and the subacute evolution of a delayed symmetrical sensorimotor peripheral neuropathy distinguish diphtheritic from all other forms of polyneuropathy. The long latency between the initial infection and the involvement of the nervous system has no clear explanation. In experimental animals, Waksman and colleagues have shown that the toxin reaches the Schwann cells in the most vascular parts of the peripheral nervous system within 24 to 48 h of infection, but its metabolic effect on cell membranes extends over a period of weeks. As in humans, the toxin produces demyelination in the proximal parts of spinal nerves, in dorsal root ganglia, and in spinal roots. The cardiac musculature and the conducting system of the heart undergo focal necroses.

The source of diphtheritic infection may be extrafaucial—a penetrating wound, skin ulcer, or umbilicus. The systemic and neurologic complications of faucial diphtheria can also be observed in the extrafaucial form of the disease, after a similar latent period. It is probable, therefore, that the toxin reaches its neural site via the bloodstream; but, in addition, some action is exerted locally, as evidenced by palatal paralysis in faucial cases and by initial weakness and sensory impairment in the neighborhood of the infected wound.

There is no specific treatment for any of the neurologic complications of diphtheria. It is generally agreed that the administration of antitoxin within 48 h of the earliest symptoms of the primary diphtheritic infection lessens the incidence and severity of complications.

The polyneuropathy of diphtheria is discussed further in [Chap. 46](#) (page 1389).

Botulism

Botulism is a rare form of food-borne illness caused by the exotoxin of *Clostridium botulinum*. Outbreaks of poisoning are more often due to home-preserved than to commercially canned products, and vegetables and home-cured ham are incriminated more commonly than any other food product. Very rarely, a contaminated wound is the source of infection. Although the disease is ubiquitous, five western states (California, Washington, Colorado, New Mexico, and Oregon) account for more than half of all reported outbreaks in the United States. *Neonatal and infantile forms* of the disease have been reported, due to absorption of the toxin formed by germination of ingested spores (rather than ingestion of preformed toxin), an important source of which is contaminated natural (raw) honey. A few adult cases may have a similar source.

It is now well established, on the basis of observations in both animals and humans, that the primary site of action of botulinus toxin is at the neuromuscular junction, more specifically on the presynaptic endings. The toxin interferes with the release of acetylcholine quanta by a mechanism like that of tetanus toxin (see previous discussion). The physiologic defect is similar to the one that characterizes the myasthenic syndrome of Lambert-Eaton (page 1547) but different from that of myasthenia gravis.

Symptoms usually appear within 12 to 36 h of ingestion of the tainted food. Anorexia, nausea, and vomiting occur in most patients. As a rule, blurred vision and diplopia are the initial neural symptoms; their association with ptosis, strabismus, and extraocular muscle palsies, particularly of the sixth nerve, may at first suggest a diagnosis of myasthenia gravis. In botulism, however, the pupils are often unreactive. Other symptoms of bulbar involvement—nasality of the voice and hoarseness, dysarthria, dysphagia, and an inability to phonate—follow in quick succession, and these, in turn, are followed by progressive weakness of muscles of the face, neck, trunk, and limbs and by respiratory insufficiency. Despite the oropharyngeal weakness, it is not unusual for the gag reflex to be retained. Tendon reflexes are lost in cases of severe weakness. These symptoms and signs evolve rapidly, over 2 to 4 days as a rule, and may be mistaken for those of the Guillain-Barré syndrome. Sensation remains intact, however, and the spinal fluid usually shows no abnormalities. Severe constipation is characteristic of botulism, due perhaps to paresis of smooth muscle of the intestine. Consciousness is retained throughout the illness unless severe degrees of anoxia develop. In the past, the mortality was consistently above 60 percent, but it has declined in recent decades, with improvements in the intensive care of acute respiratory failure and the effectiveness of *C. botulinum* antitoxins.

The clinical diagnosis can be confirmed by electrophysiologic studies (reduced amplitude of evoked muscle potentials and an increase in amplitude with rapid repetitive nerve stimulation). In patients who recover, improvement begins within a few weeks, first in ocular movement, then in other cranial nerve function. Complete recovery of paralyzed limb and trunk musculature may take many months.

The three types of botulinus toxin, A, B, and E, cannot be distinguished by their clinical effects alone, so that the patient should receive the trivalent antiserum as soon as the clinical diagnosis is made. This antitoxin can be obtained from the Centers for Disease Control and Prevention, Atlanta. An initial dose of 10,000 units is given intravenously after intradermal testing for sensitivity to horse serum, followed by daily doses of 50,000 units intramuscularly until improvement begins.

Guanidine hydrochloride (50 mg/kg) has reportedly been useful in reversing the weakness of limb and extraocular muscles. Antitoxin and guanidine probably change the course of the illness relatively little, and recovery, in the final analysis, depends upon the effectiveness of respiratory care, maintenance of fluid and electrolyte balance, prevention of infection, and so on.

The skilled injection of small quantities of botulinus toxin (Botox) into a muscle will weaken or paralyze it for weeks to months. Advantage is taken of this phenomenon in the treatment of the localized dystonias (page 114).

POISONING DUE TO PLANTS, VENOMS, BITES, AND STINGS

Ergotism

Ergotism is the name applied to poisoning with ergot, a drug derived from the rye fungus *Claviceps purpurea*. Ergot is used therapeutically to control postpartum hemorrhage due to uterine atony; one of its alkaloids, ergotamine, is a frequently used drug in the treatment of migraine, and a class of dopamine agonists used in the treatment of Parkinson disease has ergot activity. Chronic overdosage of the drug is the usual cause of ergotism; acute overdosage in the postpartum state or in the treatment of migraine may cause an alarming rise in blood pressure.

Two types of ergotism are recognized: *gangrenous*, due to a vasospastic, occlusive process in the small arteries of the extremities, and *convulsive*, or *neurogenic* ergotism. The latter is characterized by fasciculations, myoclonus, and spasms of muscles, followed by seizures. In nonfatal cases, a tabes-like neurologic syndrome may develop, with loss of knee and ankle jerks, ataxia, and impairment of deep and superficial sensation. The pathologic changes are said to consist of degeneration of the posterior columns, dorsal roots, and peripheral nerves, but they have been poorly described. The relation of these changes to ergot poisoning is not clear, since most of the cases have occurred in areas where malnutrition was endemic. The authors have had no experience with this condition.

Lathyrism

Lathyrism is a neurologic syndrome characterized by the relatively acute onset of pain, paresthesias, and weakness in the lower extremities, progressing to a permanent spastic paraplegia. It is a serious medical problem in India and in some North African countries and is probably due to a toxin contained in the chickling

vetch, *Lathyrus*, a legume that is consumed in excess during periods of famine. This disorder is discussed further with the spinal cord diseases (page 1336).

Mushroom Poisoning

The gathering of wild mushrooms, a popular pastime in late summer and early fall, always carries with it the danger of poisoning. As many as one hundred species of mushrooms are poisonous. Most of them cause only transient gastrointestinal symptoms, but some elaborate toxins that can be fatal. The most important of these toxins are the cyclopeptides, which are contained in several species of *Amanita phalloides* and *muscaria* and account for more than 90 percent of fatal mushroom poisonings. These toxins disrupt RNA metabolism, causing hepatic and renal necrosis. Symptoms of poisoning with *Amanita* usually appear between 10 and 14 h after ingestion and consist of nausea, vomiting, colicky pain, and diarrhea, followed by irritability, restlessness, ataxia, hallucinations, convulsions, and coma. There may be added evidence of a polymyopathy presenting as flaccid areflexic paralysis, high serum CK, diminished EMG potentials, and fiber necrosis.

Other important toxins are methylhydrazine (contained in the *cyromitra* species) and muscarine (*inocybe* and *clitocybe* species). The former gives rise to a clinical picture much like that caused by the cyclopeptides. The symptoms of muscarine poisoning, which appear within 30 to 60 min of ingestion, are essentially those of parasympathetic stimulation—miosis, lacrimation, salivation, nausea, vomiting, diarrhea, perspiration, bradycardia, and hypotension. Tremor, seizures, and delirium occur in cases of severe poisoning.

The mushroom toxins have no effective antidotes. If vomiting has not occurred, it should be induced with ipecac, following which activated charcoal should be administered orally in order to bind what toxin remains in the gastrointestinal tract. A local poison control center may help identify the poisonous mushroom and its toxin. Even more important, the gathering and ingestion of field varieties of mushrooms should be left to those absolutely certain of their identity.

Buckthorn Poisoning

A rapidly progressive and sometimes fatal paralysis follows the ingestion of the small fruit of the buckthorn shrub that is indigenous to northern Mexico and the neighboring parts of the United States. The responsible toxin causes a predominantly motor polyneuropathy, probably of axonal type. Except for a normal spinal fluid protein concentration, the disorder closely resembles Guillain-Barré syndrome and tick paralysis, and its recognition depends upon awareness of ingestion of the fruit in endemic areas.

Neurotoxin Fish Poisoning (Ciguatera)

Ingestion of marine toxins that block neural sodium channels is a common form of poisoning throughout coastal areas and islands of the world. It results from eating fish that have fed on toxin-containing microscopic dinoflagelates. Reef fish and shellfish are subject to high concentrations of the organisms during periodic upswings in the population of the dinoflagelates, which may be so profuse as to color the surrounding water (red tide). Although the toxins differ (tetrodotoxin, pufferfish; ciguatoxin, snails; saxitoxin and brevetoxin, shellfish), the neurologic and gastrointestinal symptoms that follow the ingestion of affected fish are similar. The initial symptoms are diarrhea, vomiting, or abdominal cramps coming on minutes to hours after the ingestion of the poisoned fish. These are followed by paresthesias that often begin periorally and then involve the limbs distally. Hot and cold sensory stimuli (e.g., ice cream) are characteristically associated with electrical-like or burning paresthesias. Muscle aches and shooting pains are also mentioned by most patients. In pufferfish poisoning and in advanced stages poisoning from other fish, weakness occurs, and there have been a few reports of coma and of respiratory failure. The recognition of this type of fish poisoning is straightforward in endemic areas, in some of which there is a seasonal clustering of cases. In tourists returning home from endemic areas or in persons consuming imported fish, the illness may be mistaken for the Guillain-Barré syndrome. Prominent perioral paresthesias should suggest the correct diagnosis. Supportive treatment is all that is required, but treatment with intravenous mannitol appears to hasten recovery.

Venoms, Bites, and Stings

These are relatively rare but nonetheless important causes of mortality in the United States. The venoms of certain species of snakes, lizards, spiders (especially the black widow spider), and scorpions contain neurotoxins that may cause a fatal depression of respiration and curare-like failure of neuromuscular transmission. In the United States, there are about 8000 poisonous snake bites per year. Some, such as the coral snake envenomation, are neurotoxic, producing pupillary dilatation, ptosis, ocular palsies, ataxia, and respiratory paralysis. Others (rattlesnakes, water moccasin snakes) cause tissue necrosis and circulatory collapse. The serious effects of *Hymenoptera stings* (bees, wasps, hornets, and fire ants) are due mainly to hypersensitivity and anaphylaxis. All of these disorders are discussed in detail in *Harrison's Principles of Internal Medicine*.

Tick Paralysis

This rare condition is the result of a toxin secreted by the gravid tick. In Canada and the northwestern United States, the wood tick *Dermacentor andersoni* is mainly responsible; in the southeastern United States it is *Dermacentor variabilis*, a dog tick, but various other ticks may occasionally have the same effect. Most cases occur in children because their small body mass makes them susceptible to the effects of only modest amounts of the toxin. The illness arises almost exclusively in the spring, when the mature ticks are most plentiful. The illness requires that the gravid tick be attached to the skin for several days.

The neurotoxin causes a generalized, flaccid, areflexic paralysis, appearing over 1 or 2 days and mimicking the Guillain-Barré syndrome. Often several days of ataxia and areflexia precede the paralysis, but sensory loss tends to be minimal. The external ophthalmoplegia that occurred in 5 of the 6 children described by Grattan-Smith et al has more often been absent in other reports; internal ophthalmoplegia and pharyngeal weakness are also known to occur, thus raising the diagnostic possibility of botulism or diphtheria. The CSF is normal and electrophysiologic studies show reduction in the amplitude of the muscle action potentials but normal or slightly slowed nerve conduction. Prominent ptosis and neck weakness may also raise the question of a neuromuscular process, but repetitive stimulation testing is normal or shows only a slight decrement or increment in some cases.

The ticks tend to attach to the hairlines or in the matted hair of the scalp, neck, and pubis, where a careful search will reveal them (nurses and electroencephalography technicians often are the ones who find them; see [Felz et al](#)). The diagnosis is most important in endemic areas and during the tick season, since the removal of the tick results in rapid and dramatic improvement.

From a neurologic point of view, the most notable disorder that follows tick bite is what has come to be known as *Lyme disease*—so named for the Connecticut community in which it was discovered. The causative agent is *Borrelia burgdorferi*, a spirochetal organism transmitted by the tick *Ixodes dammini*. The disorder is discussed fully with other infectious diseases in [Chap. 32](#) and in [Chap. 46](#), with the neuropathies.

HEAVY METALS

Lead

The causes and clinical manifestations of lead poisoning are quite different in children and adults.

Lead Poisoning in Children In the United States, the disease occurs most often in 1- to 3-year-old children who inhabit urban slum areas where old, deteriorated housing prevails. (Lead paint was used in most houses built before 1940 and in many built before 1960.) The chewing of leaded paint, the most common sources of which are windowsills and painted plaster walls, and its compulsive ingestion (pica), are the important factors in the causation of lead poisoning. The development of an acute encephalopathy is the most serious complication, leading to death in 5 to 20 percent of cases and to permanent neurologic and mental sequelae in more than 25 percent of survivors.

Clinical Manifestations These develop over a period of 3 to 6 weeks. The child becomes anorectic, less playful and less alert, and more irritable. These symptoms may be misinterpreted as a behavior disorder or mental retardation. Intermittent vomiting, vague abdominal pain, clumsiness, and ataxia may be added. If these early signs of intoxication are not recognized and the child continues to ingest lead, more flagrant signs of acute encephalopathy may develop—most frequently in the summer months, for reasons that are not understood. Vomiting becomes more persistent, apathy progresses to drowsiness and stupor interspersed with periods of hyperirritability, and finally seizures, papilledema, and coma supervene. This syndrome evolves in a period of a week or less and most rapidly in children under 2 years of age; in older children, it is more likely to develop in recurrent and less severe episodes. This clinical syndrome must be distinguished from tuberculous

meningitis, viral meningoencephalitis, and the various conditions causing acute increased intracranial pressure. Usually, in lead encephalopathy, the CSF is under increased pressure and may show a slight lymphocytic pleocytosis and elevated protein, but glucose values are normal. It follows that lumbar puncture should be done with caution and only if it is essential for diagnosis.

In children who die of acute lead encephalopathy, the brain is massively swollen, with herniation of the temporal lobes and cerebellum, multiple microscopic ischemic foci in the cerebrum and cerebellum, and endothelial damage and deposition of proteinaceous material and mononuclear inflammatory cells around many of the small blood vessels.

Diagnosis Since the symptoms of plumbism are nonspecific, the diagnosis depends upon an appreciation of the causative factors, a high index of suspicion, and certain laboratory tests. The presence of lead lines at the metaphyses of long bones and basophilic stippling of red cells are too inconstant to be relied upon, but basophilic stippling of bone marrow normoblasts is uniformly increased. Impairment of heme synthesis, which is exquisitely sensitive to the toxic effects of lead, results in the increased excretion of urinary coproporphyrin (UCP) and of d-aminolevulinic acid (ALA). These urinary indices and the lead concentrations in the serum bear an imperfect relationship to the clinical manifestations. In the test for UCP, which is readily performed in the clinic and emergency department, a few milliliters of urine are acidified with acetic acid and shaken with an equal volume of ether; if coproporphyrin is present, the ether layer will reveal a reddish fluorescence under a Wood's lamp. This test is strongly positive when the whole blood concentration of lead exceeds 80 µg/dL. The diagnosis can be confirmed by promoting lead excretion with calcium disodium edetate (CaNa₂ EDTA), given in three doses (25 mg/kg) at 8-h intervals. Excretion of over 500 mg in 24 h is indicative of plumbism. The measurement of zinc protoporphyrin (ZPP) in the blood is another reliable means of determining the presence and degree of lead exposure. The binding of erythrocyte protoporphyrin to zinc occurs when lead impairs the normal binding of erythrocyte protoporphyrin to iron. Elevated ZPP can also occur when access to iron is limited by other conditions, such as iron deficiency anemia.

Treatment At blood lead concentrations of 70 µg/dL, symptoms may be minimal, but acute encephalopathy may occur abruptly and unpredictably, for which reason the child should be hospitalized for chelation therapy. Some children with a blood lead level of 50 µg/dL may have symptoms of severe encephalopathy, whereas others may be asymptomatic. In the latter case, an attempt should be made to discover and remove the source of lead intoxication and the child should be reexamined at frequent intervals. The seriousness of lead encephalopathy is indicated by the fact that most of the children who become stuporous or comatose remain mentally retarded despite treatment. The physician's aim, therefore, is to *institute treatment before the severe symptoms of encephalopathy have become manifest*.

The plan of therapy includes the following:

1. Establishment of urinary flow, following which intravenous fluid therapy is restricted to basal water and electrolyte requirements.
2. In cases of acute encephalopathy, combined chelation therapy with 2,3-dimercaptopropanol (BAL, 12 to 24 mg/kg) and CaNa₂ EDTA (0.5 to 1.5 g/m² body surface area) for 5 to 7 days. This is followed by a course of oral penicillamine (40 mg/kg, not exceeding 1 g per day). In acute cases the goal is to reduce the serum lead levels below 40 µg/dL. Once the absorption of lead has ceased, chelating agents remove lead only from soft tissues and not from bone, where most of the lead is stored. Any intercurrent illness may result in a mobilization of lead from bones and soft tissues and an exacerbation of symptoms of lead intoxication.
3. Repeated doses of mannitol for relief of cerebral edema.
4. Microcytic hypochromic anemia is treated with iron once the chelating agents have been discontinued.
5. Seizures are best controlled with intravenous diazepam or midazolam.

Prevention The prevention of reintoxication (or intoxication) demands that the child be removed from the source of lead. Although this is axiomatic, it is often difficult to accomplish, despite the best efforts of local health departments and hospital and city social workers. Nevertheless, an attempt to correct the environmental factor must be made in each case. Such attempts, among other things, have resulted in a marked decrease in the incidence of acute lead encephalopathy in the past two decades. Although florid examples of this encephalopathy are now uncommon, undue exposure to lead (blood levels > 30 µg/dL) remains inordinately prevalent and a continuing source of concern to public health authorities. As to the levels that pose a danger to the child, there is still some uncertainty. Rutter, who reviewed all of the evidence up to 1980, concluded that persistent blood levels above 40 µg/dL may cause slight cognitive impairment and, less certainly, an increased risk of behavioral difficulties. The oral lead chelator *succimer* is approved for outpatient treatment of asymptomatic children with blood lead levels higher than 45 µg/dL. A 3-week course of treatment is given, with weekly monitoring of blood lead levels to identify lead mobilization from bones and soft tissues ([Jorgensen](#)).

In 1988, on the basis of epidemiologic and experimental studies in the United States, Europe, and Australia, the Agency for Toxic Substances and Disease Registry set a much lower threshold for neurobehavioral toxicity (10 to 15 µg/dL). They estimated that 3 to 4 million American children have blood levels in excess of this amount. Needleman et al studied the long-term effects of low doses of lead in asymptomatic children, 132 of whom had had demonstrable levels of lead in the dentin of shed teeth (average 24 µg/dL). Eleven years later, the children were found to have behavioral abnormalities proportionate to their early lead levels. In comparison to a normal population, more had dropped out of school and more had lower vocabulary and grammatical reasoning scores, more reading difficulty, poorer hand-eye coordination performance, slower finger-tapping rates, and longer reaction times. The authors claimed to have eliminated other confounding variables such as lower social class and genetic factors. These findings have been confirmed by the long-term studies of Baghurst et al (see also [Mahaffey](#)).

Lead Intoxication in Adults This is much less common than in children. The hazards to adults are exposure to dust of inorganic lead salts and to fumes resulting from the burning of lead or processes that require the remelting of lead. Painting, printing, pottery glazing, lead smelting, and storage battery manufacturing are the industries in which these hazards are likeliest to occur. Miners and brass foundry and garage workers (during automobile radiator repair, when soldered joints are heated) are the ones most at risk.

The usual manifestations of lead poisoning in adults are colic, anemia, and peripheral neuropathy. Encephalopathy is decidedly rare; usually it results from consumption of illicit liquor contaminated by lead solder in the pipes of stills. Lead colic, frequently precipitated by an intercurrent infection or by alcohol intoxication, is characterized by severe, poorly localized abdominal pain, often with rigidity of abdominal muscles but without fever or leukocytosis. The pain responds to the intravenous injection of calcium salts, at least temporarily, but very little to morphine. Mild anemia is common. A black line of lead sulfide may develop along the gingival margins. Peripheral neuropathy, usually a bilateral wrist drop, is a rare manifestation and is discussed on page 1393.

The diagnostic tests for plumbism in children are generally applicable to adults, with the exception of bone films, which are of no value in the latter. Also, the treatment of adults with chelating agents follows the same principles as in children.

Intoxication with tetraethyl and tetramethyl (organic) lead, used as additives in gasoline, presents a special problem. It is caused by inhalation of gasoline fumes and has occurred most often in workers who clean gasoline storage tanks. Insomnia, irritability, delusions, and hallucinations are the usual clinical manifestations, and a maniacal state may develop. The hematologic abnormalities of inorganic lead poisoning are not found, and chelating agents are of no value in treatment. Organic lead poisoning is usually reversible, but fatalities have been reported. The pathologic changes have not been well described.

Arsenic

In the past, medications such as Fowler's solution (potassium arsenite) and the arsphenamines, used in the treatment of syphilis, were frequent causes of intoxication, but now the most common cause is the suicidal or accidental ingestion of herbicides, insecticides, or rodenticides containing copper acetoarsenate (Paris green) or calcium or lead arsenate. In rural areas, arsenic-containing insecticide sprays are a common source of poisoning. Arsenic is used also in the manufacture of paints, enamels, and metals; as a disinfectant for skins and furs; and also in galvanizing, soldering, etching, and lead plating. Occasional cases of poisoning are reported in relation to these occupations. Arsenic is still contained in some topical creams that are used in the treatment of psoriasis and other skin disorders.

Arsenic exerts its toxic effects by reacting with the sulfhydryl radicals of certain enzymes necessary for cellular metabolism. The effects on the nervous system are those of an encephalopathy or peripheral neuropathy. The latter may be the product of chronic poisoning or may become manifest between 1 and 2 weeks after recovery from the effects of acute poisoning. It takes the form of a distal axonopathy and is described on page 1393. In our cases of arsenical polyneuropathy a distal sensorimotor areflexic syndrome has developed subacutely. At autopsy there was a dying back pattern of myelin and axons with macrophage and Schwann cell reactions and chromatolysis of motor neurons and sensory ganglion cells. The CNS appeared normal.

The symptoms of encephalopathy (headache, drowsiness, mental confusion, delirium, and convulsive seizures) may also occur as part of acute or chronic intoxication. In the latter case, they are accompanied by weakness and muscular aching, hemolysis, chills and fever (in patients exposed to arsine gas), mucosal irritation, a diffuse scaly desquamation, and transverse white lines, 1 to 2 mm in width, above the lunula of each fingernail (Mees lines). Acute poisoning by the oral

route is associated with severe gastrointestinal symptoms, circulatory collapse, and death in a large proportion of patients. The CSF is normal. Examination of the brain in such cases discloses numerous punctate hemorrhages in the white matter. Microscopically, the lesions consist of pericapillary zones of degeneration, which, in turn, are ringed by red cells (brain purpura or encephalorrhagia, incorrectly referred to as hemorrhagic encephalitis). These neuropathologic changes are not specific for arsenical poisoning but have been observed in such diverse conditions as pneumonia, gram-negative bacillary septicemia from urinary tract infections, sulfonamide and phosgene poisoning, dysentery, disseminated intravascular coagulation, and others.

The diagnosis of arsenical poisoning depends upon the demonstration of increased levels of arsenic in the hair and urine. Arsenic is deposited in the hair within 2 weeks of exposure and may remain fixed there for years. Concentrations of more than 0.1 mg arsenic per 100 mg hair are indicative of poisoning. Arsenic also remains within bones for long periods and is slowly excreted in the urine and feces. Excretion of more than 0.1 mg arsenic per liter of urine is considered abnormal; levels greater than 1 mg/L may occur soon after acute exposure. The CSF protein level may be raised (50 to 100 mg/dL).

Acute poisoning is treated by gastric lavage, vasopressor agents, dimercaprol (BAL), maintenance of renal perfusion, and exchange transfusions if massive hemoglobinuria occurs. Once polyneuropathy has occurred, it is little affected by treatment with BAL, but other manifestations of chronic arsenical poisoning respond favorably. There has been a gradual recovery from the polyneuropathy in our cases.

Manganese

Manganese poisoning results from the chronic inhalation and ingestion of manganese particles and occurs in miners of manganese ore and in workers who separate manganese from other ore. Several clinical syndromes have been observed. The initial stages of intoxication may be marked by a prolonged confusional-hallucinatory state. Later, the symptoms are predominantly extrapyramidal. They are often described as parkinsonian in type, but in the patients seen by the authors, the resemblance was not close: an odd gait (“cock walk”), dystonia and rigidity of the trunk, postural instability, and falling backwards were features seen in two South American miners. Others, however, have reported stiffness and awkwardness of the limbs, often with tremor of the hands, “cogwheel” phenomenon, gross rhythmic movements of the trunk and head, and retropulsive and propulsive gait. Corticospinal and corticobulbar signs may be added. Progressive weakness, fatigability, and sleepiness as well as psychiatric symptoms (manganese madness) are other clinical features. Rarely, severe axial rigidity and dystonia, like those of Wilson disease, are said to have been the outstanding manifestations.

Neuronal loss and gliosis, affecting mainly the pallidum and striatum but also the frontoparietal and cerebellar cortex and hypothalamus, have been described, but the pathologic changes have not been carefully studied.

The neurologic abnormalities have not responded to treatment with chelating agents. In the chronic “dystonic form” of manganese intoxication, dramatic and sustained improvement has been reported with the administration of L-dopa; patients with the more common “parkinsonian type” of manganese intoxication have shown only slight if any improvement with L-dopa.

Mercury

Mercury poisoning arises in two forms, one due to inorganic compounds (elemental or mercury salt) and the other, more dangerous, to organic mercury. Among the latter, methyl mercury compounds give rise to a wide array of serious neurologic symptoms that may be delayed for days or weeks after exposure, including tremor of the extremities, tongue, and lips; mental confusion; and a progressive cerebellar syndrome, with ataxia of gait and of the arms, intention tremor, and dysarthria. Chorea and choreoathetosis and parkinsonian facies have also been described. Changes in mood and behavior are prominent, consisting at first of subjective weakness and fatigability and later of extreme depression and lethargy alternating with irritability. This *delayed form of subacute mercury poisoning* has been reported in chemical laboratory workers after exposure to methyl mercury compounds. These agents, particularly dimethyl mercury, are extremely hazardous because they are absorbed transdermally and by inhalation, allowing severe toxicity to occur with even brief contact. In a fatal case of a chemist reported by Nierenberg et al, a rapidly progressive ataxia and encephalopathy developed 154 days after exposure; the cerebellum was most severely affected, with loss of all cortical neuronal elements, and the calcarine fissures were affected in a pattern similar to the Minamata cases described below. The pathologic changes are characterized by neuronal loss and gliosis of the calcarine cortex and to a lesser extent of other parts of the cerebral cortex and a striking degeneration of the granular layer of the cerebellar cortex, with relative sparing of the Purkinje cells.

The chronic form of inorganic mercury poisoning occurs in persons exposed to large amounts of the metal used in the manufacture of thermometers, mirrors, incandescent lights, x-ray machines, and vacuum pumps. Since mercury volatilizes at room temperature, it readily contaminates the air and then condenses on the skin and respiratory mucous membranes. Nitrate of mercury, used in the manufacture of felt hats (“mad hatters”), and phenyl mercury, used in the paper, pulp, and electrochemical industries, are other sources of intoxication. Paresthesias, lassitude, confusion, incoordination, and intention tremor are characteristic, and, with continued exposure, delirium occurs. Headache, various bodily pains, visual and hearing symptoms, and corticospinal signs may be added, but their pathologic basis is unknown. The term *erethism* was coined to describe the timidity, memory loss, and insomnia that were said to be characteristic of chronic intoxication. Unless the exposure has been of minimal amounts over a long period of time, gastrointestinal disturbances are prone to occur (anorexia, weight loss) as well as stomatitis and gingivitis with loosening of the teeth. Acute exposure to inorganic mercury in larger amounts is even more corrosive to the gastrointestinal system and produces nausea, vomiting, hematemesis, abdominal pain, and bloody diarrhea as well as renal tubular necrosis.

Isolated instances of polyneuropathy associated with exposure to mercury have also been reported ([Albers](#) et al, [Agocs](#) et al) and may be responsible for the paresthesias that accompany most cases and the acrodynic syndrome described below. The inhalation of vaporized mercury as a result of extensive dental work has been alleged to affect the peripheral nerves, but the connection is very tenuous.

The presence of mercury in industrial waste has contaminated many sources of water supply and fish, which are ingested by humans and cause mercurial poisoning. So-called Minamata disease is a case in point. Between 1953 and 1956, a large number of villagers living near Minamata Bay in Kyushu Island, Japan, were afflicted with a syndrome of chronic mercurialism, traced to the ingestion of fish that had been contaminated with industrial wastes containing methyl mercury. Concentric constriction of the visual fields, hearing loss, cerebellar ataxia, postural and action tremors, and sensory impairment of the legs and arms and sometimes of the tongue and lips were the usual clinical manifestations. The syndrome evolved over a few weeks. Pathologically there was diffuse neuronal loss in both cerebral and cerebellar cortices, most marked in the anterior parts of the calcarine cortex and granule cell layer of the cerebellum. CT scans in survivors, years after the mass poisoning, disclosed bilaterally symmetrical areas of decreased attenuation in the visual cortex and diffuse atrophy of the cerebellar hemispheres and vermis, especially the inferior vermis ([Tokuomi](#) et al).

A painful neuropathy of children (acrodynia) has been traced to mercury exposure from interior latex paint, to calomel (mercurous chloride), to teething powders, and to a mercuric fungicide used in washing diapers ([Agocs](#) et al, [Clarkson](#)). Albers et al observed the appearance of symptoms (mild decrease in strength, tremor, and incoordination) 20 to 35 years after exposure to elemental mercury. These authors believe that the natural neuronal attrition with aging had unmasked the neurologic disorder.

In the *treatment* of chronic mercury poisoning, penicillamine has been the drug of choice, since it can be administered orally and appears to chelate mercury selectively, with less effect on copper, which is an essential element in many metabolic processes. Dimercaptosuccinic acid (succimer), which is also given orally and has few side effects, will probably prove to be a superior form of treatment ([Clarkson](#)). Because it increases the concentration of mercury in the brain, BAL is an unsuitable chelating agent.

Phosphorus and Organophosphate Poisoning

Nervous system function may be deranged as part of acute and frequently fatal poisoning with inorganic phosphorus compounds (found in rat poisons, roach powders, and matchheads). More important clinically is poisoning with organophosphorus compounds, the best known of which is triorthocresyl phosphate (TOCP).

Organophosphates are widely used as *insecticides*. Since 1945, approximately 15,000 individual compounds have come into use. Certain ones, such as tetraethylpyrophosphate, have been the cause of major outbreaks of neurologic disorder, especially in children. These substances have an acute anticholinesterase effect but no delayed neurotoxic action. Chlorophos, which is a 1-hydroxy-2,2,2-trichlorethylphosphonate, has, in addition, a delayed action, as does TOCP.

The *immediate* anticholinesterase effect manifests itself by headache, vomiting, sweating, abdominal cramps, salivation, wheezing secondary to bronchial spasm, miosis, and muscular weakness and twitching. Most of these symptoms can be reversed by administration of atropine and pralidoxine. Some of the patients suffer a

delayed effect, 2 to 5 weeks following acute organophosphorus insecticide poisoning. This takes the form of a distal symmetrical sensorimotor (predominantly motor) polyneuropathy, progressing to atrophy. Recovery occurs to a variable degree, and then, in patients poisoned with TOCP, signs of corticospinal damage become detectable. The severity of paralysis and its permanence vary with the dosage of TOCP. Whether a polyneuropathy can arise without the preceding symptoms of cholinergic toxicity is debated; however, based on a review of the subject and a study of 11 patients exposed to these agents, 3 of whom later acquired sensory neuropathy, Moretto and Lotti express the view that such an occurrence must be rare.

In addition to the acute and delayed neurotoxic effects of organophosphorus, an *intermediate syndrome* has been described ([Senanayake and Karalliedde](#)). Symptoms come on 24 to 96 h after the acute cholinergic phase and consist of weakness or paralysis of proximal limb muscles, neck flexors, motor cranial nerves, and respiratory muscles. Respiratory paralysis may prove fatal. In patients who survive, the paralytic symptoms last for 2 to 3 weeks and then subside. The intermediate and delayed symptoms do not respond to atropine or other drugs.

Several striking outbreaks of TOCP poisoning have been reported. During the latter part of the prohibition era and to a lesser extent thereafter, outbreaks of “jake paralysis” were traced to drinking an extract of Jamaica ginger that had been contaminated with TOCP. The authors have examined several “ginger jake” cases many years later and found only signs of corticospinal disease. Another outbreak occurred in Morocco, in 1959, when lubricating oil containing TOCP was used deliberately to dilute olive oil. Several other outbreaks have been caused by the ingestion of grain and cooking oil that had been stored in inadequately cleaned containers previously used for storing TOCP.

The effect of TOCP on the peripheral nervous system has been studied extensively in experimental animals. In cats, there occurs a dying back from the terminal ends of the largest and longest medullated motor nerve fibers, including those from the annulospiral endings of the muscle spindles ([Cavanagh and Patangia](#)). The long fiber tracts of the spinal cord show a similar dying-back phenomenon. Abnormal membrane-bound vesicles and tubules were observed by Prineas to accumulate in axoplasm before degeneration. These effects have been traced to the inhibitory action of TOCP on esterases. There is still uncertainty as to the details of these reactions, and no treatment for the prevention or control of the neurotoxic effects has been devised.

Thallium

In the late nineteenth century, thallium was used medicinally in the treatment of venereal disease, ringworm, and tuberculosis and later in rodenticides and insecticides. Poisoning was fairly common. Sporadic instances of poisoning still occur, usually as a result of accidental or suicidal ingestion of thallium-containing rodenticides and rarely from overuse of depilatory agents. Patients who survive the effects of acute poisoning develop a rapidly progressive and painful sensory polyneuropathy, optic atrophy, and occasionally ophthalmoplegia—followed, 15 to 30 days after ingestion, by diffuse alopecia. The latter feature should always suggest the diagnosis of thallium poisoning, which can be confirmed by finding this metallic element in the urine. Two of our patients had only a severe sensory and mild motor polyneuropathy and alopecia, from which they were recovering a month later. It is not uncommon for the neuropathy to have a painful component involving acral regions. The condition can end fatally. The use of potassium chloride by mouth may hasten thallium excretion.

Other Metals

Iron, antimony, tin, aluminum, zinc, barium, bismuth, copper, silver, gold, platinum, and lithium may all produce serious degrees of intoxication. The major manifestations in each case are gastrointestinal or renal, but certain neurologic symptoms—notably headache, irritability, confusional psychosis, stupor, coma, and convulsions—may be observed in cases of profound poisoning, often as terminal events.

Gold preparations, which are still used occasionally in the treatment of arthritis, may, after several months of treatment, give rise to focal or generalized myokymia and a rapidly progressive, symmetrical polyneuropathy ([Katrak](#) et al). The adverse effects of *platinum* are discussed below, with the antineoplastic agents. *Lithium* has been discussed earlier.

Attention has already been drawn to the possible causative role of *aluminum intoxication* in so-called dialysis dementia or encephalopathy (page 1189). Removal of aluminum from the water used in renal dialysis has practically eliminated this disorder. However, the neuropathologic changes in experimental aluminum intoxication (see below) are not those observed in dialysis dementia. Perl and colleagues have reported the accumulation of aluminum in tangle-bearing neurons of patients with Alzheimer disease and in the Guamanian Parkinson–dementia–amyotrophic lateral sclerosis (ALS) complex. However, analysis of neuritic plaques by nuclear microscopy, without using chemical stains, failed to demonstrate the presence of aluminum ([Landsberg](#) et al). The significance of these findings remains to be determined. Longstreth and colleagues have described a progressive neurologic disorder consisting of intention tremor, incoordination, and spastic paraparesis in three patients who had worked for more than 12 years in the same pot room of an aluminum smelting plant. Similar cases attributable to aluminum intoxication have not been reported, however.

Organic compounds of *tin* may seriously damage the nervous system. Diffuse edema of the white matter of the brain and spinal cord has been produced experimentally with *triethyltin*. Presumably this was the basis of the mass poisoning produced by a triethyltin-contaminated drug called Stalinon. The illness was characterized by greatly elevated intracranial pressure and by a spinal cord lesion in some cases ([Alajouanine](#) et al). *Trimethyltin* intoxication is much rarer; seizures are the main manifestation. Experimental studies in rats have shown neuronal loss in the hippocampus, largely *sparing* the Sommer sector, with later involvement of neurons in the pyriform cortex and amygdala (see review by [Le-Quesne](#)).

A stereotyped episodic encephalopathy has been associated with *bismuth intoxication*, usually arising from the ingestion of bismuth subgallate. Large outbreaks have been reported in Australia and France ([Burns](#) et al, [Buge](#) et al). The onset of the neurologic disturbance is usually subacute, with a mild and fluctuating confusion, somnolence, difficulty in concentration, tremulousness, and sometimes hallucinations and delusions. With continued ingestion of bismuth, there occurs a rapid (24- to 48-h) worsening of the confusion and tremulousness, along with diffuse myoclonic jerks, seizures, ataxia, and inability to stand or walk. These symptoms regress over a period of a few days to weeks when the bismuth is withdrawn, but some patients have died of acute intoxication. High concentrations of bismuth were found in the cerebral and cerebellar cortices and in the nuclear masses throughout the brain. These concentrations can be recognized as hyperdensities in the CT scan ([Buge](#) et al).

Industrial Toxins

Some of these, the heavy metals, have already been considered. In addition, a large number of synthetic organic compounds are widely used in industry and are frequent sources of toxicity, and the list is constantly being expanded. The reader is referred to the references at the end of the chapter, particularly to the most current text, edited by Spencer and Schaumburg, for details concerning these compounds; here we can do little more than enumerate the most important ones: chlorinated diphenyls (e.g., DDT) or chlorinated polycyclic compounds (Kepone), used as insecticides; diethylene dioxide (Dioxane); carbon disulfide; the halogenated hydrocarbons (methyl chloride, tetrachloroethane, carbon tetrachloride, trichloroethylene, and methyl bromide); naphthalene (used in moth repellants); benzene (gasoline); benzene and its derivatives [toluene, xylene, nitrobenzene, phenol, and amyl acetate (banana oil)] and the hexacarbon solvents (*n*-hexane and methyl *n*-butyl ketone).

The acute toxic effects of these substances are much the same from one compound to another. In general, the primary effect is on nonneurologic structures. Neural symptoms consist of varying combinations of headache, restlessness, drowsiness, confusion, delirium, coma, and convulsions, which, as a rule, occur late in the illness or preterminally. Some of these industrial toxins (carbon disulfide, carbon tetrachloride and tetrachloroethane, acrylamide, *n*-hexane) may cause polyneuropathy, which becomes evident with recovery from acute toxicity. Extrapyramidal symptoms may result from chronic exposure to carbon disulfide. A syndrome of persistent fatigue, lack of stamina, inability to concentrate, poor memory, and irritability has also been attributed to chronic exposure to solvents, but these symptoms are quite nonspecific, and evidence for such a syndrome is unsupported by convincing experimental or epidemiologic studies.

Of the aforementioned industrial toxins, the ones most likely to cause neurologic disease are *toluene* (methyl benzene) and the *hexacarbons*. The chronic inhalation of fumes containing toluene (usually in glue, contact cement, or certain brands of spray paint) may lead to severe and irreversible tremor and cerebellar ataxia, affecting movements of the eyes (opsoclonus, ocular dysmetria) and limbs as well as stance and gait. Cognitive impairment is usually associated; corticospinal tract signs, progressive optic neuropathy, sensorineural hearing loss, and hyposmia occur in some patients. Generalized cerebral atrophy and particularly cerebellar atrophy are evident in CT scans ([Fornazzari](#) et al, [Hormes](#) et al). Also, it has become apparent that acute toluene intoxication is an important cause of seizures, hallucinations, and coma in children ([King](#) et al).

The prolonged exposure to high concentrations of *n*-hexane or methyl-*n*-butyl ketone may cause a sensorimotor neuropathy, so-called glue-sniffer's neuropathy (page

1394). These solvents are metabolized to 2,5-hexanedione, which is the agent that damages the peripheral nerves. The neuropathy may result from exposure in certain industrial settings (mainly the manufacture of vinyl products) or, more often, from the deliberate inhalation of vapors from solvents, lacquers, glue, or glue thinners containing *n*-hexane (see also [Chap. 46](#)). Impure trichloroethylene, through its breakdown product dichloroacetylene, has a predilection for the trigeminal nerve, which can be damaged selectively.

ANTINEOPLASTIC AND IMMUNOSUPPRESSIVE AGENTS

The increasing use of potent antineoplastic agents has given rise to a diverse group of neurologic complications, the most important of which are summarized below. A more detailed account of these agents—as well as the neurologic complications of corticosteroid therapy, immunosuppression, and radiation—can be found in the monograph edited by Rottenberg and in the review of Tuxen and Hansen. The neurotoxic effects of certain agents used in the treatment of brain tumors are also considered in [Chap. 31](#).

Vincristine

This drug is used in the treatment of acute lymphoblastic leukemia, lymphomas, and some solid tumors. Its most important toxic side effect, and the one that limits its use as a chemotherapeutic agent, is a peripheral neuropathy. Paresthesias of the feet, hands, or both may occur within a few weeks of the beginning of treatment; with continued use of the drug, a progressive symmetrical neuropathy evolves (mainly sensory with reflex loss). Cranial nerves are affected less frequently; ptosis and lateral rectus, facial, and vocal cord palsies are the usual manifestations. Autonomic nervous system function may also be affected: constipation and impotence are frequent complications; orthostatic hypotension, atonicity of the bladder, and adynamic ileus are less frequent. The polyneuropathy is described more fully on page 1394. Inappropriate antidiuretic hormone secretion and seizures have been reported but are relatively uncommon.

The neural complications of *vinblastine* are similar to those of vincristine but are usually avoided because bone marrow suppression limits the dose of the drug that can safely be employed. *Vinorelbine* is a more recently introduced semisynthetic vinca alkaloid. It has much the same antitumor activity as vincristine but is said to be less toxic.

Procarbazine

This drug, originally synthesized as an MAO inhibitor, is now an important oral agent in the treatment of Hodgkin disease and other lymphomas, bronchogenic carcinoma, and malignant gliomas. It has proved to be especially effective in the treatment of oligodendrogliomas. Neural complications are infrequent and usually take the form of somnolence, confusion, agitation, and depression. Diffuse aching pain in proximal muscles of the limbs and mild symptoms and signs of polyneuropathy occur in 10 to 15 percent of patients treated with relatively high doses. A reversible ataxia has also been described. Procarbazine, taken in conjunction with phenothiazines, barbiturates, narcotics, or alcohol, may produce serious degrees of oversedation. Other toxic reactions, such as orthostatic hypotension, are related to the MAO inhibitory action of procarbazine.

L-Asparaginase

L-Asparaginase is an enzymatic inhibitor of protein synthesis and is used in the treatment of acute lymphoblastic leukemia. Drowsiness, confusion, delirium, stupor, coma, and diffuse EEG slowing are the common neurologic effects and are dose-related and cumulative. They may occur within a day of onset of treatment and clear quickly when the drug is withdrawn, or they may be delayed in onset, in which case they may persist for several weeks. These abnormalities are at least in part attributable to the systemic metabolic derangements induced by L-asparaginase, including liver dysfunction.

In recent years, increasing attention has been drawn to cerebrovascular complications of L-asparaginase therapy, including ischemic and hemorrhagic infarction and cerebral venous and dural sinus thrombosis. Fineberg and Swenson have analyzed the clinical features of 38 such cases. These cerebrovascular complications are attributable to transient deficiencies in plasma proteins that are important in coagulation and fibrinolysis.

5-Fluorouracil

This is a pyrimidine analogue, used mainly in the treatment of cancer of the breast, ovary, and gastrointestinal tract. A small proportion of patients receiving this drug develop dizziness, cerebellar ataxia of the trunk and the extremities, dysarthria, and nystagmus—symptoms that are much the same as those produced by cytarabine (Ara-C; see page 1285). These abnormalities must be distinguished from metastatic involvement of the cerebellum and paraneoplastic cerebellar degeneration. The drug effects are usually mild and subside within 1 to 6 weeks after discontinuation of therapy. The anatomic basis of this cerebellar syndrome is not known.

Methotrexate

Administered in conventional oral or intravenous doses, methotrexate (MTX) is not neurotoxic. However, given intrathecally to treat meningeal leukemia or carcinomatosis, MTX commonly causes aseptic meningitis, with headache, nausea and vomiting, stiff neck, fever, and cells in the spinal fluid. Very rarely, probably as an idiosyncratic response to the drug, intrathecal administration results in an acute paraplegia that may be permanent. The pathology of this condition has not been studied. The most serious of the neurologic problems associated with chemotherapy is a necrotizing leukoencephalopathy or leukomyelopathy caused by MTX when given in combination with cranial or neuraxis radiation therapy (page 729). This develops several months after repeated intrathecal or high systemic doses of MTX. The full-blown syndrome consists of the insidious evolution of dementia, pseudobulbar palsy, ataxia, focal cerebral cortical deficits, or paraplegia. The brain shows disseminated foci of coagulation necrosis of white matter, usually periventricular, which can be detected with CT and MRI. Yet unsettled is the role of MTX in the development of asymptomatic CT scan abnormalities or of mild neurologic abnormalities in children with acute lymphoblastic leukemia given intrathecal MTX and cranial irradiation as prophylaxis; the same uncertainty pertains to the relation of this white matter change to that seen with the use of cyclosporin, as discussed further on. Mineralizing microangiopathy (fibrosis and calcification of small vessels, mainly in the basal ganglia) is yet another complication of MTX therapy. It may occur with MTX treatment or with cranial irradiation but is particularly common when both forms of treatment are combined. To the present authors these lesions have the features of the coagulative necrosis of radiation encephalopathy.

Cisplatin

Cisplatin, a heavy metal that inhibits DNA synthesis, is effective in the treatment of gonadal and head and neck tumors as well as carcinoma of the bladder, prostate, and breast. The dose-limiting factors in its use are nephrotoxicity and vomiting and a peripheral neuropathy (see also page 1394). The latter manifests itself by numbness and tingling in fingers and toes, sometimes painful—symptoms that are being observed with increasing frequency. This toxic manifestation appears to be related to the total amount administered, and it usually improves slowly after the drug has been discontinued. Biopsies of peripheral nerve have shown a primary axonal degeneration. Approximately one-third of patients receiving this drug also experience tinnitus or high-frequency hearing loss (4000 to 8000 Hz) or both. This ototoxicity is also dose-related, cumulative, and only occasionally reversible. Some preventative effect for cisplatin neuropathy has been claimed for the melanocortin compound ACTH (4-9), but the benefits in a trial by Gerristen and colleagues were quite small and probably do not justify its administration on a routine basis. Retrobulbar neuritis occurs rarely. Seizures associated with drug-induced hyponatremia and hypomagnesemia have been reported.

Paclitaxel and Docetaxel

Taxol (paclitaxel) and Taxotere (docetaxel) are new anticancer drugs derived from the bark of the western yew. Both are particularly useful in the treatment of ovarian and breast cancer, but they have a wide range of antineoplastic activities. A purely or predominantly sensory neuropathy is a common complication. These drugs are thought to cause neuropathy by their action as inhibitors of the depolymerization of tubulin, thereby promoting excessive microtubule assembly within the axon. The neuropathy is dose-dependent, occurring with doses greater than 200 mg/m² of paclitaxel and at a wide range of dose levels for docetaxel (generally over 600 mg/m²). Symptoms may begin 1 to 3 days following the first dose and affect the feet and hands simultaneously. Autonomic neuropathy (orthostatic hypotension) may occur as well. The neuropathy is axonal in type, with secondary demyelination, and is at least partially reversible after discontinuation of the drug.

The Nitrosoureas

Carmustine (BCNU) and lomustine (CCNU) are nitrosoureas used to treat malignant cerebral gliomas. They are not neurotoxic when given in conventional

intravenous doses, but intracarotid injection of the drugs may cause orbital, eye, and neck pain, focal seizures, confusion, and possibly focal neurologic deficits. Postmortem examinations of patients who had been treated with BCNU have disclosed diffuse foci of swollen axis cylinders and myelin vacuolization and a diffuse vasculopathy characterized by fibrinoid necrosis and microthrombi ([Burger](#) et al, [Kleinschmidt-de Masters](#)).

Cytarabine (Ara-C)

This drug, long used in the treatment of acute nonlymphocytic leukemia, is not neurotoxic when given in systemic daily doses of 100 to 200 mg/m². The administration of very high doses of Ara-C (up to 30 times the usual dose) has been shown to induce remissions in patients refractory to conventional treatment, but it also produces a severe degree of cerebellar degeneration in a considerable proportion of cases (4 of 24 patients reported by Winkelman and Hines). Ataxia of gait and limbs, dysarthria, and nystagmus develop as early as 5 to 7 days after the beginning of high-dose treatment and worsen rapidly. Postmortem examination has disclosed a diffuse degeneration of Purkinje cells, most marked in the depths of the folia, as well as a patchy necrosis of the cerebellar cortex affecting all the cellular elements. Other patients receiving high-dose Ara-C develop a mild, reversible cerebellar syndrome with the same clinical features as the irreversible one. Patients more than 50 years of age are said to be six times more likely to develop cerebellar degeneration than those younger than 50; therefore the former should be treated with a lower dosage than the latter ([Herzig](#) et al).

Cyclosporine and Tacrolimus (FK-506)

These immunosuppressive drugs are used to prevent transplant rejection and to treat aplastic anemia and certain intrinsic immune diseases. Tremor is perhaps the most frequent side effect, particularly of tacrolimus, and myoclonus may be added. Sometimes these impart a stuttering character to speech. Headache and insomnia are common. Seizures may be a manifestation of toxicity, but the cause may lie with the other complications of organ transplantation and immunosuppression. The neurologic effects of these drugs have been reviewed by Wijdicks. A syndrome resembling hypertensive encephalopathy—headache, vomiting, confusion, seizures, and visual loss (cortical blindness)—may follow the use of either drug (see page 903). The appearance on CT scans and MRI of symmetrical signal and density changes mainly in the posterior white matter likewise conforms to the pattern that is seen in hypertensive encephalopathy. Lesions may also appear subcortically in the frontal and parietal lobes. Hinchey and colleagues describe several such cases and suggest that cyclosporin alters the blood-brain barrier and that the fluid overload and hypertension that may accompany the use of cyclosporin may cause the syndrome and the radiologic changes. A variety of psychotic syndromes with delusions, paranoia, and visual hallucinations has also been ascribed to the use of these drugs (see [Wijdicks](#)).

Thalidomide

Despite the catastrophic effects of thalidomide on the developing fetus (following its introduction as a soporific in 1957), this drug has now found several specific uses in the treatment of immunologic and infectious diseases. It is highly effective in the treatment of leprosy, erythema nodosum, and the oral ulcerations of AIDS and Behçet disease. Experimental uses include suppression of graft-versus-host reactions and inhibition of blood vessel proliferation in vascular tumors. A dose-dependent sensory neuropathy is the limiting factor in its use, and serial electrophysiologic testing is recommended if the medication is to be prescribed for protracted periods. Of course, it must never be given to a woman who is or might be pregnant.

Antibiotics and Other Drugs

Numerous antibiotics, cardioactive medications, and other drugs may have adverse effects on the central or peripheral nervous system. Some of the latter are addressed on page 1395. Here we mention only that penicillin and its derivatives such as imipenem and cephalosporins are capable of causing seizures when high serum concentrations are attained. This occurs most often in patients with renal failure.

Other important examples are optic neuropathy due to ethambutol toxicity; ototoxicity and neuromuscular blockade from aminoglycoside antibiotics (page 1549); neuropathy, encephalopathy, and an Antabuse-like reaction to alcohol in patients taking metronidazole; INH neuropathy and optic neuropathy and possibly peripheral neuropathy due to chloramphenicol.

The most notorious of this group of drugs was *clioquinol*, which was sold as Entero-vioform and used in many parts of the world to prevent traveler's diarrhea and as a treatment for chronic gastroenteritis. In 1971, clinical observations began to appear in medical journals of a subacute myelo-opticoneuropathy (SMON). During the 1960s, more than 10,000 cases of this neurotoxic disease were collected in Japan by Tsubaki et al. Usually the disease began with a gastrointestinal disturbance, followed by ascending numbness and weakness of the legs, paralysis of sphincters, and autonomic disorder. Later, vision was affected.

The onset was acute in about two-thirds of the cases and subacute in the remainder. The occurrence of these neurologic complications was related to the prolonged use of clioquinol. In Japan the drug was withdrawn from the market, and the incidence of SMON immediately fell, supporting the theory that it was caused by clioquinol.

Recovery is usually incomplete. Two patients seen by the authors several years after onset of the disease had been left with optic atrophy and a spastic-ataxic paraparesis.

[Chapter References](#)

Diseases of the nervous system may be confined to the spinal cord, where they produce a number of distinctive syndromes. The latter relate to special physiologic and anatomic features of the cord, such as its prominent function in sensorimotor conduction and relatively primitive reflex activity; its long, cylindrical shape; its small cross-sectional size; its tight envelopment by meninges; the peripheral location of myelinated fibers, next to the pia; the special arrangement of its blood vessels; and its particular relationships to the vertebral column.

Woolsey and Young estimate that there are about thirty diseases known to affect the spinal cord, of which half are seen with regularity. These diseases express themselves by a number of readily recognized syndromes and, as will be evident, certain ones preferentially evoke one syndrome and not others. The syndromic grouping of the spinal cord disorders, which is in keeping with the general plan of this book, facilitates clinical diagnosis and reduces the number of ancillary examinations needed for confirmation.

The main syndromes to be considered in this chapter are (1) a transverse sensorimotor myelopathy that may be complete or involve most of the ascending and descending tracts; (2) a combined painful radicular and transverse cord syndrome; (3) the hemicord (Brown-Séquard) syndrome and its variants; (4) a ventral cord syndrome, sparing posterior column function; (5) a high cervical–foramen magnum syndrome; (6) a central cord or syringomyelic syndrome; (7) a syndrome of the conus medullaris; and (8) a syndrome of the cauda equina (see also pages 1332 to 1334). It is also useful to distinguish between lesions within the cord (*intramedullary*) and those that compress the cord from without (*extramedullary*). Certain processes have a proclivity to cause one or another of these syndromes, and each of them will be considered in the course of exposition of the major categories of spinal cord disease.

Some of the anatomic and physiologic considerations pertinent to an understanding of disorders of the cord (and of the spine) can be found in [Chap. 3](#), [Chap. 9](#) (particularly [Fig. 9-4](#)), and [Chap. 11](#), on motor paralysis, somatic sensation, and back pain, respectively.

THE SYNDROME OF ACUTE PARAPLEGIA OR QUADRIPLEGIA DUE TO COMPLETE TRANSVERSE LESIONS OF THE SPINAL CORD

This syndrome is best considered in relation to trauma, its most frequent cause, but it occurs also as a result of infarction or hemorrhage and with rapidly advancing compressive, necrotizing, demyelinating, or inflammatory lesions (myelitis). Each of these categories of acute spinal cord disease is discussed in the following pages. For convenience of exposition we have included radiation myelopathy, which evolves subacutely.

Trauma to the Spine and Spinal Cord

Throughout recorded medical history, signal advances in the understanding of spinal cord disease have coincided with periods of warfare. The first thoroughly documented study of the effects of sudden total cord transection was that of Theodor Kocher in 1896, based on his observations of 15 patients. During World War I, Riddoch—and later Head and Riddoch—gave the classic descriptions of spinal transection in humans; [Lhermitte and Guillain](#) and Barré made additional observations. Little could be done for these patients, however. Fully 80 percent died in the first few weeks (from infections), and survival was possible only if the spinal cord lesion was a partial one. World War II marked a turning point in the understanding and management of spinal cord injuries. The advent of antibiotics and the ability to control skin, bladder, and pulmonary infections permitted the survival of unprecedented numbers of soldiers with spinal cord injuries and provided the opportunity for long-term observation. In special centers, such as the Long Beach, Hines, and West Roxbury Veterans Administration Hospitals in the United States and the Stoke Mandeville National Spinal Injuries Centre in England, the care and rehabilitation of the paraplegic were perfected. Studies conducted in these centers have greatly enhanced our knowledge of the functional capacity of the chronically isolated spinal cord. [Kuhn](#), [Munro](#), [Martin and Davis](#), [Guttmann](#), [Pollock](#), and their associates, listed in the references, have made particularly important contributions to this subject.

Mechanisms of Spine and Spinal Cord Injury Although trauma may involve the spinal cord alone, the vertebral column is almost invariably injured at the same time. Often there is an associated head injury as well, as pointed out in [Chap. 35](#).

A useful classification of *spinal injuries* is one that divides them into fracture-dislocations, pure fractures, and pure dislocations. The relative frequency of these types is about 3:1:1. Except for bullet, shrapnel, and stab wounds, a direct blow to the spine is a relatively uncommon cause of serious spinal cord injury. In civilian life, most spinal injuries are the result of *force applied at a distance* from the site of spinal fracture and dislocation. All three types of spinal injury mentioned above are produced by a similar mechanism, usually a vertical compression of the spinal column to which anteroﬂexion is almost immediately added (anterohyperﬂexion injury); or, the mechanism may be one of vertical compression and retrohyperﬂexion (commonly referred to as hyperextension). The most important variables in the mechanics of vertebral injury are the nature of the bones at the level of the injury and the intensity, direction, and point of impact of the force.

If the cranium is struck by a hard object at high velocity, a skull fracture occurs, the force of the injury being absorbed mainly by the elastic quality of the skull. If the traumatizing force is relatively soft yet unyielding, the spine, and particularly its most mobile (cervical) portion, will be the part injured. If the neck happens to be rigid and straight and the force is applied quickly to the head, the atlas and the odontoid process of the axis may break. If the force is applied less quickly, an element of

flexion or extension is added.

In the case of severe forward *flexion injury*, the head is bent sharply forward when the force is applied. The adjacent vertebrae are forced together at the level of maximum stress. The anteroinferior edge of the upper vertebral body is driven into the one below, sometimes splitting it in two. The posterior part of the fractured body is displaced backward and compresses the cord. Concomitantly, there is tearing of the interspinous and posterior longitudinal ligaments. Less severe degrees of anteroflexion injury produce only dislocation. Vulnerability to the effects of anteroflexion (and to some extent to retroflexion injuries) is increased by the presence of cervical spondylosis or ankylosing spondylitis or a congenital stenosis of the spinal canal.

In *hyperextension injuries*, the mechanism is one of vertical compression with the head in an extended position. Stress is mainly on the posterior elements of the midcervical vertebrae (C4 to C6)—i.e., on their laminae and pedicles, which may be fractured, unilaterally or bilaterally—and on the anterior ligaments. This dual disruption in the spinal architecture allows for displacement of one vertebral body on an adjacent one. The dislocation results in the cord being caught between the laminae of the lower vertebra and the body of the one above. Damage that primarily affects the central cord (as described further on) is usually due to an extension injury.

Finally, it should be pointed out that a hyperextension injury to the spinal cord may occur without apparent damage or misalignment of the vertebrae when viewed radiologically. In these instances the spinal cord damage, which can be nonetheless profound and permanent, is caused by a sudden inward bulge of the ligamentum flavum or a transient vertebral dislocation and then realignment. This type of spinal cord damage, without radiologic evidence of fracture or dislocation, is particularly common in children.

CT, MRI, and plain lateral spine films are all satisfactory means of demonstrating the vertebral injury, but the tearing and bulging of ligaments from vertebral dislocation is dependably demonstrated only by MRI (or by contrast myelography) and can only be inferred from the spinal displacement. Radiologic studies during cautious flexion or extension of the neck are the only way one can demonstrate instability from ligamentous injury alone.

Another mechanism of cord and root injury, involving extremes of extension and flexion of the neck, is so-called *whiplash* or *recoil injury*. This type of injury is most often the result of an automobile accident. When a vehicle is struck sharply from behind, the head of the occupant is flung back uncontrollably; or, if a fast-moving vehicle stops abruptly, there is sudden forward flexion of the neck, followed by retroflexion. Under these conditions occipitounuchal and sternocleidomastoid muscles and other supporting structures of the neck and head are affected much more often than the spinal cord or roots. Nevertheless, in rare instances, quadriplegia, temporary or permanent, results from a violent whiplash injury. The exact mechanism of neural injury in these circumstances is not clear; perhaps there is a transient posterior dislocation of a vertebral body, a momentary buckling of the ligamentum flavum, or retropulsion of the intervertebral disc into the spinal canal. Again, the presence of a congenitally narrow cervical spinal canal or of spinal diseases such as cervical spondylosis, rheumatoid arthritis, or ankylosing spondylitis greatly adds to the hazard of damage to the cord or roots. Preexisting spondylotic symptoms may be aggravated and become the source of chronic pain. Also, there are examples of spinal cord compression that result from the persistent hyperextension of the cervical spine during a protracted period of coma. Arterial hypotension may be an added factor in particular instances. This combination accounts for some of the cases of quadriplegia in opiate or other drug addicts following a period of sustained unresponsiveness ([Eli et al](#)).

A special type of spinal cord injury, occurring most often in wartime, is one in which a high-velocity missile penetrates the vertebral canal and damages the spinal cord directly. In some cases the missile strikes the vertebral column without entering the spinal canal but virtually shatters the contents of the dural tube or produces lesser degrees of impairment of spinal cord function. Rarely, the transmitted shock wave will cause a paralysis of spinal cord function that is completely reversible in a day or two (*spinal cord concussion*, described further on).

Acute traumatic paralysis may also be the consequence of a vascular mechanism. Fibrocartilaginous emboli from an intervertebral disc that has ruptured into radicular arteries or veins of the spinal cord may cause infarction. Or, a traumatic dissecting aneurysm of the aorta may occlude the segmental arteries of the spinal cord, as in the cases reported by [Weisman and Adams](#) and by [Kneisley](#).

An analysis of 2000 cases of spinal injury collected from the medical literature by [Jefferson](#) showed that most vertebral injuries occurred at the levels of the first and second cervical, fourth to sixth cervical, and eleventh thoracic to second lumbar vertebrae. Industrial accidents most often involved the thoracolumbar vertebrae. Impact to the head with the neck flexed or sharply retroflexed, as mentioned above, was the main cause of injuries to the cervical region. These are not only the most mobile portions of the vertebral column but also the regions in which the cervical and lumbar enlargements of the cord greatly reduce the space between neural and bony structures. The thoracic cord is relatively small and its spinal canal is capacious; additional protection is provided by the high articular facets (making dislocation difficult) and limitations in anterior movement imposed by the thoracic cage.

In the authors' experience, the usual circumstances of spinal cord injury have been motor vehicle accidents, falls (mainly during a state of alcoholic intoxication), gunshot or stab wounds, diving accidents, motorcycle accidents, crushing industrial injuries, and birth injury, in that order of frequency. The majority of the fatal cases were associated with fracture-dislocations or dislocations of the cervical spine. Respiration is paralyzed by lesions of the C1, C2, and C3 segments. Among nonfatal cases, fracture-dislocation of the lower cervical spine is the most frequent established mechanism of spinal cord injury in civilian life. In the United States, the annual incidence of spinal cord injury is from 5 to 5.5 cases per 100,000 population. Males predominate (4:1). Each year about 3500 persons die in close relation to their injury, and another 5000 are left with complete or nearly complete loss of spinal cord function.

Pathology of Spinal Cord Injury As a result of squeezing or shearing of the spinal cord, there is destruction of gray and white matter and a variable amount of hemorrhage, chiefly in the more vascular central parts. These changes, best designated as *traumatic necrosis* of the spinal cord, are maximal at the level of injury and one or two segments above and below it. Rarely is the cord cut in two, and seldom is the pia-arachnoid lacerated. Separation of concomitant pathologic entities—such as hematomyelia, concussion, contusion, and hematorrhachis (bleeding into the spinal canal)—is of little value either clinically or pathologically. As a lesion heals, it leaves a gliotic focus or cavitation with variable amounts of hemosiderin and iron pigment. Progressive meningeal fibrosis and cavitation (traumatic syringomyelia) will sometimes develop after an interval of months or years and lead to a delayed central or transverse cord syndrome (see further on).

In most traumatic lesions, the central part of the spinal cord, with its vascular gray matter, suffers greater injury than the peripheral parts. In some instances, the lesion is virtually restricted to the anterior and posterior gray matter, giving rise to segmental weakness and sensory loss in the arms with few long tract signs. This has been called the *central cervical cord syndrome* (or Schneider syndrome, see further on). Fragments of the syndrome are not uncommon as transient phenomena that reverse over several days.

As with most lesions, the total clinical effect is compounded of an irreversible structural component and a reversible disorder of function, each of which may vary in degree. The extent and permanence of the clinical manifestations are determined by the relative proportions of these two elements.

Experimental Spinal Cord Injury Investigation of the pathophysiology of acute spinal cord injury dates from the experimental studies of Allen, in the early 1900s. His method consisted of dropping graded weights onto the dura-covered thoracic cord of surgically prepared animals. The technique was refined over the years by precise measurements of the velocity, force, and direction of the dropped weights.

This type of impact on the cord, of sufficient severity to render the animal immediately paraplegic and abolish sensory evoked responses from structures below the lesion, indicates that action potentials can no longer be conducted across the injured spinal cord segment. No histologic changes, by either light or electron microscopy, can be detected for several minutes after impact. The earliest tissue alterations consist of hyperemia and small hemorrhages in the central gray matter. By 1 h, the microscopic hemorrhages coalesce and become macroscopically visible and tissue oxygen saturation is diminished in the region. Within 4 h, the central part of the cord is swollen and a spreading edema pervades the surrounding white matter; however, irrevocable white matter necrosis may not be evident for up to 8 h, an observation that has led to numerous strategies designed to spare long tracts. Surgical intervention to minimize white matter edema—such as laminectomy and myelotomy—spinal cord cooling, hyperbaric exposure, and the administration of pharmacologic measures have been tried but appear to have no effects on the evolving lesion. The early administration of high-dose corticosteroids has been a widely used mode of treatment, but the clinical benefits are questionable. Certain mechanisms that are currently thought to be operative in the death of cerebral neurons have also been invoked in spinal cord injury. These include glutamate release and exposure of neurons to calcium and agents that release free radicals. The latter mechanism may explain the salutary effect of high doses of corticosteroids rather than the ostensible effect of these drugs on edema. There are controversies concerning the putative role of accumulated vasoactive amines and opioids on the damaged segments of cord. Osterholm postulated that the initial event in acute impact injury was the release of norepinephrine from injured neurons in the central gray matter and that the subsequent vasoconstriction was responsible for both the central hemorrhagic and lateral white matter lesions. Later experimental work failed to substantiate these suggestions. Also, the contention that opioid release at the moment of trauma plays an important role in tissue damage has not been confirmed

experimentally. The main problem with all the experimental work is that it does not truly reproduce the various types of spinal injury in humans.

Clinical Effects of Spinal Cord Injury When the spinal cord is suddenly and completely or almost completely severed, three disorders of function are at once evident: (1) all voluntary movement in parts of the body below the lesion is immediately and permanently lost; (2) all sensation from the lower (aboral) parts is abolished; and (3) reflex functions in all segments of the isolated spinal cord are suspended. The last effect, called *spinal shock*, involves tendon as well as autonomic reflexes; it is of variable duration (1 to 6 weeks as a rule) and is so dramatic that Riddoch used it as a basis for dividing the clinical effects of spinal cord transection into two stages: (1) spinal shock or areflexia and (2) heightened reflex activity. The separation of these two stages is not as sharp as this statement might imply but is nevertheless fundamental. Less complete lesions of the spinal cord may result in little or no spinal shock, and the same is true of any type of lesion that develops slowly.

Stage of Spinal Shock or Areflexia The loss of motor function at the time of injury—quadriplegia (better termed tetraplegia) with lesions of the fourth to fifth cervical segments, paraplegia with lesions of the thoracic cord—is accompanied by atonic paralysis of bladder and bowel, gastric atony, loss of sensation below a level corresponding to the spinal cord lesion, muscular flaccidity, and complete or almost complete suppression of all spinal segmental reflex activity below the lesion. The neural elements below the lesion fail to perform their normal function because of their sudden separation from those of higher levels. Impaired also in the segments below the lesion is the control of autonomic function. Vasomotor tone, sweating, and piloerection in the lower parts of the body are temporarily abolished. Systemic hypotension may be severe and contribute to the spinal cord damage. The lower extremities lose heat if left uncovered, and they swell if dependent. The skin is dry and pale, and ulcerations may develop over bony prominences. The sphincters of the bladder and the rectum remain contracted to some degree due to the loss of inhibitory influence of higher central nervous system (CNS) centers, but the detrusor of the bladder and smooth muscle of the rectum are atonic. Urine accumulates until the intravesicular pressure is sufficient to overcome the sphincters; then dribbles escape (overflow incontinence). There is also passive distention of the bowel, retention of feces, and absence of peristalsis (paralytic ileus). Genital reflexes (penile erection, bulbocavernosus reflex, contraction of dartos muscle) are abolished or profoundly depressed.

The duration of the stage of complete areflexia varies considerably. In a small number (5 of Kuhn's 29 patients, for example) it is permanent, or only fragmentary reflex activity is regained many months or years after the injury. In such patients the spinal segments below the level of transection may have themselves been injured—perhaps by a vascular mechanism, although this explanation is unproven. More likely there is a loss of the brainstem-spinal facilitatory mechanisms and an increase in inhibitory activity in the isolated segments as indicated below. In some patients, minimal genital and flexor reflex activity can be detected within a few days of the injury. In the majority of patients, this minimal reflex activity appears within a period of 1 to 6 weeks. Usually the bulbocavernosus reflex is the first to return. Noxious stimulation of the plantar surfaces evokes a tremulous twitching and brief flexion or extension movements of the great toes. Contraction of the anal sphincter can be elicited by plantar or perianal stimulation, and other genital reflexes reappear at about the same time.

The explanation of spinal shock, which is brief in submammalian forms and more lasting in higher mammals, especially in primates, is believed to be the sudden interruption of suprasegmental descending fiber systems that normally keep the spinal motor neurons in a continuous state of subliminal depolarization (ready to respond). In the cat and monkey, Fulton found the facilitatory tracts in question to be the reticulospinal and vestibulospinal. Subsequent studies showed that in monkeys, some degree of spinal shock can result from interruption of the corticospinal tracts alone. This cannot be the significant factor, however, at least in humans, because spinal shock may be very mild or inevident as a result of acute cerebral and brainstem lesions that interrupt the corticospinal tracts. F waves, which reflect the functioning of the motor neurons of a segment of the cord, are suppressed until spasticity supervenes, at which time they become excessively easy to elicit. Interest in recent years has focused on a possible role for neurotransmitters (catecholamines, endorphins, substance P, and 5-hydroxytryptamine). As already indicated, the claim that naloxone and the endogenous opiate antagonist thyrotropin releasing factor might reduce the extent of an acute spinal cord lesion has not been corroborated. Clonidine, a noradrenergic receptor activator, is reported to reduce flexor spasms and spasticity and to restore the balance between excitatory and inhibitory activity, allowing the spinal reflex generator for locomotion to function ([Woolsey and Young](#)).

Stage of Heightened Reflex Activity This is the very familiar neurologic state that emerges within several weeks or months after the spinal injury. Usually, after a few weeks, the reflex responses to stimulation, which are initially minimal and unsustained, become stronger and more easily elicitable and come to include additional and more proximal muscles. Gradually the typical pattern of heightened flexion reflexes emerges: dorsiflexion of the big toe (Babinski sign); fanning of the other toes; and later, flexion or slow withdrawal movements of the foot, leg, and thigh with contraction of the tensor fascia lata (triple flexion). Tactile stimulation of the foot may suffice as a stimulus, but a painful stimulus is more effective. The Achilles reflexes and then the patellar reflexes return. Retention of urine becomes less complete, and at irregular intervals urine is expelled by active contractions of the detrusor muscle. Reflex defecation also begins. After several months the withdrawal reflexes become greatly exaggerated, to the point of flexor spasms, and may be accompanied by profuse sweating, piloerection, and automatic emptying of the bladder (occasionally of the rectum). This is the “mass reflex,” which is evoked by stimulation of the skin of the legs or by some interoceptive stimulus, such as a full bladder. Varying degrees of heightened flexor reflex activity may last for years. Heat-induced sweating is defective, but reflex-evoked (“spinal”) sweating may be profuse (see [Kneisley](#)). Presumably, in such cases the lateral horn cells in much of the thoracic cord are still viable and disinhibited. Above the level of the lesion, thermoregulatory sweating may be exaggerated and is accompanied by cutaneous flushing, pounding headache, hypertension, and reflex bradycardia. This syndrome (“autonomic dysreflexia”) is episodic and occurs in response to a particular stimulus, such as a distended bladder or rectum. It has been ascribed to the reflex release of adrenalin from the adrenal medulla and of norepinephrine from the disinhibited sympathetic terminals caudal to the lesion.

Extensor reflexes eventually develop in most cases (18 of 22 of Kuhn's patients who survived more than 2 years), but their appearance does not lead to the abolition of the flexor reflexes. The overactivity of extensor muscles may appear as early as 6 months after the injury, but this only happens, as a rule, after the flexor responses are fully developed. Extensor responses are at first manifest in certain muscles of the hip and thigh and later of the leg. In a few patients extensor reflexes are organized into support reactions sufficient to permit *spinal standing*. Kuhn observed that extensor movements were at first provoked most readily by a sudden shift from a sitting to a supine position and later by proprioceptive stimuli (squeezing of the thigh muscles) and tactile stimuli from wide areas. Marshall, in a study of 44 patients with chronic spastic paraplegia of spinal origin, found all possible combinations of flexor and extensor reflexes; the type of reflex obtained was determined by the intensity and duration of the stimulus (a mild prolonged noxious stimulus evoked an ipsilateral extensor reflex; an intense brief stimulus, a flexor response).

From these observations one would suspect that the ultimate posture of the legs—flexion or extension—does not depend solely on the completeness or incompleteness of the spinal cord lesion, as originally postulated by [Riddoch](#). The development of *paraplegia in flexion* relates also to the level of the lesion, being seen most often with cervical lesions and progressively less often with more caudal ones. Repeated flexor spasms, which are more frequent with higher lesions, and the ensuing contractures ultimately determine a fixed flexor posture. Conversely, reduction of flexor spasms by elimination of nociceptive stimuli (infected bladder, decubiti, etc.) favors an extensor posture of the legs (*paraplegia in extension*). According to Guttmann, the positioning of the limbs during the early stages of paraplegia greatly influences their ultimate posture. Thus, prolonged fixation of the paralyzed limbs in adduction and semiflexion favors subsequent paraplegia in flexion. Placing the patient prone or placing the limbs in abduction and extension facilitates the development of predominantly extensor postures. Nevertheless, strong and persistent extensor postures are observed only with partial lesions of the spinal cord.

Of some interest is the fact that many patients report sensory symptoms in segments of the body below the level of their transection. Thus, a tactile stimulus above the level of the lesion may be felt below the transection (synesthesia). Patients describe a variety of paresthesias, the most common being a dull, burning pain in the lower back and abdomen, buttocks, and perineum. We have encountered patients in whom aching testicular or rectal pain was the main problem. The pain may be intense and last for a year or longer, after which it gradually subsides. It may persist after rhizotomy but can be abolished by anesthetizing the stump of the proximal (upper) segment of the spinal cord, according to Pollock and his collaborators. Transmission of sensation over splanchnic afferents to levels of the spinal cord above the lesion, the conventional explanation, is therefore not the most plausible one.

The overactivity of neurons in the isolated segments of the spinal cord has several explanations. One assumes that suprasegmental inhibitory influences have been removed by the transection, so that afferent sensory impulses evoke exaggerated nocifensive and phasic and tonic myotatic reflexes. But isolated neurons also become hypersensitive to neurotransmitters. Since the early experiments of Cannon and Rosenblueth, it has been known that section of sympathetic motor fibers leaves the denervated structures hypersensitive to epinephrine; these authors also found the motor neurons in the isolated spinal segments to be abnormally sensitive to acetylcholine.

Various combinations of residual deficits (of lower and upper motor neurons and sensory neurons) are to be expected. Some of the resulting clinical pictures are complete or incomplete voluntary motor paralysis; a flaccid atrophic paralysis of upper limb muscles (if appropriate segments of gray matter are destroyed) with spastic weakness of the legs (amyotrophy with spastic paraplegia in flexion or extension); a partial or rarely a complete Brown-Séquard syndrome (pages 62 and 161); and each of these with variable sensory impairment in the legs and arms. High cervical lesions may result in extreme and prolonged tonic spasms of the legs due to release of tonic myotatic reflexes. Under these circumstances, attempted voluntary movement may excite intense contraction of all flexor and extensor muscles lasting for several minutes. Segmental damage in the low cervical or lumbar gray matter, destroying inhibitory Renshaw neurons, may release activity of remaining anterior horn cells, leading to spinal segmental spasticity. Any residual symptoms persisting after 6 months are likely to be permanent, although in a small proportion

of patients some return of function (particularly sensation) is possible after this time. Loss of motor and sensory function above the lesion, coming on years after the trauma, occurs occasionally and is due to an enlarging cavity in the proximal segment of the cord (see further on, under “ [Syringomyelia](#)”).

Transient Cord Injury (Spinal Cord Concussion) These terms refer to a transient loss of motor and/or sensory function of the spinal cord that recovers within minutes or hours but sometimes persists for a day or several days. In most instances the symptoms are already diminishing and no neurologic abnormalities are found at the time of the first examination. There are a number of such transient syndromes; bibrachial weakness; quadriparesis (occasionally hemiparesis); paresthesias and dysesthesias in a similar distribution to the weakness; or sensory symptoms alone (“burning hands syndrome”). In the first and last of these the central gray matter of the cervical cord is implicated. It is assumed that the cord undergoes some form of elastic deformation when the head is struck at the vertex or frontally and the cervical spine is compressed or hyperextended; however, the same effects can be produced by direct blows to the spine or forceful falls flat on the back and occasionally by a sharp fall on the tip of the coccyx. Little is known of the pathologic changes or the mechanisms that underlie these transient and reversible syndromes.

Spinal cord concussion is observed most frequently in athletes engaged in contact sports (football, rugby, and hockey). A congenitally narrow cervical canal is thought to predispose to spinal cord concussion and to increase the risk of recurrence. As with cerebral concussion, particularly if there have been previous concussions, a difficult decision arises—whether to allow resumption of competitive sports. There are no reliable data on which to base this decision—only guidelines that favor continued participation if the deficit has been brief. Certainly, it is advisable in most cases to be certain that spinal instability has not been induced by the injury. This can be ascertained by obtaining flexion and extension radiographs of the affected spinal region. The subject is reviewed by [Zwimpfer and Bernstein](#).

Central Cord Syndrome (Schneider Syndrome and “Cruciate Paralysis”) In the acute central cord lesion, the loss of motor function is characteristically more severe in the upper limbs than in the lower ones and particularly severe in the hands. Bladder dysfunction with urinary retention occurs in some of the cases, and sensory loss is often slight (hyperpathia over the shoulders and arms may be the only sensory abnormality). Damage of the centrally situated gray matter (motor and sensory neurons) may leave an atrophic, areflexic paralysis and a segmental loss of pain and thermal sensation from interruption of crossing pain and thermal fibers. Retroflexion injuries of the head and neck are the ones most often associated with the central cord syndrome, but hematomyelia, necrotizing myelitis, fibrocartilagenous embolism, and possibly infarction due to compression of the vertebral artery in the medullary-cervical region are other causes (Morse).

According to [Dickman and colleagues](#), approximately 4 percent of patients who survive high cervical cord injuries demonstrate what these authors refer to as “cruciate paralysis.” The latter state is similar to the central cord syndrome except that the weakness is even more selective, being practically limited to the arms, a feature that is attributable to the segregation of corticospinal fibers to the arms (rostral) and to the legs (caudal) within the decussation. The patients described in the literature have had injuries, basically contusions, of the C1–C2 region. The arm weakness may be asymmetrical or even unilateral; sensory loss is inconsistent.

Examination of the Spine-Injured Patient The level of the spinal cord and vertebral lesions can be determined from the clinical findings. A complete paralysis of the arms and legs usually indicates a fracture or dislocation at the fourth to fifth cervical vertebrae. If the legs are paralyzed and the arms can still be abducted and flexed, the lesion is likely to be at the fifth to sixth cervical vertebrae. Paralysis of the legs and only the hands indicates a lesion at the sixth to seventh cervical level. Below the cervical region, the spinal cord segments and roots are not opposite their similarly numbered vertebrae ([Fig. 44-1](#)). The spinal cord ends opposite the first lumbar vertebra, usually at its rostral border. Vertebral lesions below this point give rise predominantly to cauda equina syndromes; these carry a better prognosis than injuries to the lower thoracic vertebrae, which involve both cord and multiple roots. The level of sensory loss on the trunk, determined by perception of pinprick, is also an accurate guide to the level of the lesion, with a few qualifications. With lesions of the lower cervical cord, even if complete, sensation may be preserved down to the nipple line, because of the contribution of the C3 and C4 cutaneous branches of the cervical plexus, which innervate skin below the clavicle. Rarely, a lesion will involve only the outermost fibers of the spinothalamic pathways, sparing the innermost ones, in which case the sensory level (to pain and temperature) will be below the level of the lesion. In all cases of spinal cord and cauda equina injury, the prognosis for recovery is more favorable if any movement or sensation is elicitable during the first 48 to 72 h.

Figure 44-1 The relationship of spinal segments and roots to the vertebral bodies and spinous processes. The cervical roots (except C8) exit through foramina above their respective vertebral bodies, and the other roots issue below these bodies. (From [Haymaker and Woodhall](#): *Peripheral Nerve Injuries*, 2nd ed. Philadelphia, Saunders, 1953, by permission.)

If the spine can be examined safely, it should be inspected for angulations or irregularities and gently percussed to elicit signs of bony injury. Collateral injury of the thorax, abdomen, and long bones must always be sought.

Management of Spinal Injury In all cases of suspected spinal injury, the immediate concern is that there be no movement (especially flexion) of the cervical spine from the moment of the accident. The patient should be placed supine on a firm, flat surface (with one person assigned to keeping the head and neck immobile) and should be transported by a vehicle that can accept the litter. Preferably, the patient should be transported by an ambulance equipped with spine boards, to which the head is rigidly fixed by straps. This provides a more effective means of immobilization than sandbags or similar objects placed on each side of the head and neck. On arrival at the hospital, it is useful to have the patient remain on the backboard until a lateral film or a CT or MRI of the cervical spine have been obtained.

A careful neurologic examination with detailed recording of motor, sensory, and sphincter function is necessary to follow the clinical progress of spinal cord injury. A common practice is to define the injury according to the standards of the American Spinal Injury Association and to assign the injury to a point on the Frankel Scale.

1. Complete: motor and sensory loss below the lesion
2. Incomplete: some sensory preservation below the zone of injury
3. Incomplete: motor and sensory sparing, but the patient is nonfunctional
4. Incomplete: motor and sensory sparing and the patient is functional (stands and walks)
5. Complete functional recovery: reflexes may be abnormal

Obviously, groups 2, 3, and 4 have a more favorable prognosis for recovery of ambulation than does group 1.

Once the degrees of injury to spine and cord have been assessed, the usual practice during the past decade has been to administer methylprednisolone in high dosage (bolus of 30 mg/kg followed by 5.4 mg/kg every hour), beginning within 8 h of the injury and continued for 23 h. This measure, according to the multicenter National Acute Spinal Cord Study ([Bracken et al](#)) resulted in a slight but significant improvement in both motor and sensory function. Despite its widespread use, the therapeutic value of this measure has not been established beyond doubt, and its value has been questioned after careful re-analysis of the data ([Nesathurai](#); [Hurlbert](#)). Also, in a small series of patients, the administration of G_{M1} ganglioside (100 mg intravenously each day from the time of the accident) was found to enhance ultimate recovery to a modest degree ([Geisler et al](#)), but again, this finding must be corroborated.

Next, radiologic examinations are undertaken to determine the alignment of vertebral bodies and pedicles, compression of the spinal cord or cauda equina due to malalignment or bone debris in the spinal canal, and the presence of tissue damage within the cord. The MRI is ideally suited to display these processes; but if it is not available and there is uncertainty regarding cord compression, myelography with CT scanning is a useful alternative. Instability of the spinal elements can often

be inferred from dislocations or from certain fractures of the pedicles, pars articularis, or transverse processes, but gentle flexion and extension of the injured areas must sometimes be undertaken and plain films obtained in each position.

If a cervical spinal cord injury is associated with vertebral dislocation, traction on the neck is necessary to secure proper alignment and maintain immobilization. This is best accomplished by use of a halo brace, which, of all the appliances used for this purpose, provides the most rigid external fixation of the cervical spine. This type of fixation is usually continued for 4 to 6 weeks, after which a rigid collar may be substituted.

In general, concerning the early surgical management of spinal cord injury, there have been two schools of thought. One, represented by [Guttmann and others](#), advocates reduction and alignment of the dislocated vertebrae by traction and immobilization until skeletal fixation is obtained, and then rehabilitation. The other school, represented by [Munro](#) and later by [Collins and Chehrizi](#), proposes early surgical decompression, correction of bony displacements, and removal of herniated disc tissue and intra- and extramedullary hemorrhage; often the spine is fixed at the same time by a bone graft or other form of stabilization. The issue of acute decompressive surgery remains contentious to the present day. Most American neurosurgeons take the less aggressive stance, delaying operation or operating only on patients with compound wounds or those with progression or worsening of the neurologic deficit despite adequate reduction and stabilization. With complete spinal cord lesions, most surgeons do not favor surgery.

The results of the conservative and aggressive surgical plans of management have been difficult to compare and have not been evaluated with modern neurologic techniques. Collins, a participant in the National Institutes of Health (NIH) study of acute management of spinal cord injury, concluded that the survival rate was increased as a result of early surgical stabilization of fractures and fixation of the spine (in addition to the usual measures for the prevention of respiratory, urinary, and cutaneous complications and the early institution of rehabilitation measures). Other neurosurgeons, however, have not been able to document a reduction in neurologic disability as a result of early operation, and they have increasingly inclined toward nonoperative management of both complete and partial spinal cord lesions (Clark; [Murphy et al](#)). In any given case, the approach must be guided by the particular features of the patient's injuries. A detailed description of the orthopedic and neurosurgical treatment of spinal fracture-dislocations is beyond the scope of a textbook of neurology but can be found in the account by [Ogilvy and Heros](#) and in the book edited by [Woolsey and Young](#), listed in the References.

The greatest risk to the patient with spinal cord injury is in the first week or 10 days, when gastric dilatation, ileus, shock, and infection are the main threats to life. According to [Messard and colleagues](#), the mortality rate falls rapidly after the first 3 months; beyond this time, 86 percent of paraplegics and 80 percent of quadriplegics will survive for 10 years or longer. In children, the survival rate is even higher ([DeVivo et al](#)). The latter authors found that the cumulative 7-year survival rate in spinal cord-injured patients (who had survived at least 24 h after injury) was 87 percent. Advanced age at the time of injury and being rendered completely quadriplegic were the worst prognostic factors.

The aftercare of patients with paraplegia is concerned with management of bladder and bowel disturbances, care of the skin, prevention of pulmonary embolism, and maintenance of nutrition. Decubitus ulcers can be prevented by frequent turning to avoid pressure necrosis, use of special mattresses, and meticulous skin care. Deep lesions require debridement and full-thickness grafting. At first continual catheterization is necessary; then, after several weeks, the bladder can be managed by intermittent catheterization once or twice daily, using a scrupulous aseptic technique. Close watch is kept for bladder infection, which is treated promptly should it occur. Bacteruria is common and does not require treatment with antibiotics unless there is associated pyuria. Morning suppositories and periodically spaced enemas are the most effective means of controlling fecal incontinence. Chronic pain (present in 30 to 50 percent of cases) requires the use of nonsteroidal anti-inflammatory medication, injections of local anesthetics, and transcutaneous nerve stimulation. A combination of carbamazepine and either clonazepam or tricyclic antidepressants may be helpful in cases of burning leg and trunk pain. Recalcitrant pain may require more aggressive therapy, such as epidural injections of analgesics or corticosteroids, but often even these measures are ineffective. Spasticity and flexor spasms may be troublesome; oral baclofen, diazepam, or tizanidine may provide some relief. In permanent spastic paraplegia with severe stiffness and adductor and flexor spasms of the legs, intrathecal baclofen, delivered by an automated pump in doses of 12 to 400 mg/day, has reportedly been helpful. The drug is believed to act at the synapses of spinal reflexes (Penn and Kroin). One must always be alert to the threat of pulmonary embolism from deep-vein thrombi, although the incidence is surprisingly low after the first several months. Physiotherapy, muscle re-education, and the proper use of braces are all important in the rehabilitation of the patient. All this is best carried out in special centers for rehabilitation of spinal cord injuries.

Posttraumatic syringomyelia is described further on (see [Fig. 44-12](#)).

Figure 44-12 T1-weighted sagittal MRI of the cervical cord, showing a posttraumatic syrinx that led to progressive clinical worsening. At operation there proved to be glial septa within the cavity.

Radiation Injury of the Spinal Cord

Delayed necrosis of the spinal cord and brain is a well-recognized sequela of radiation therapy for tumors in these regions and in the thorax and neck. The peripheral nerves are more resistant to this adverse effect, although we have observed, as have others, an early reversible and a late progressive and permanent sensorimotor neuropathy coming on several months or years after irradiation. Finally, a lower motor neuron lesion, presumably due to injury to the gray matter of the spinal cord, may also follow radiation therapy.

Transient Myelopathy The “early” type of radiation myelopathy (appearing 3 to 6 months after radiotherapy) is characterized mainly by paresthesias in the extremities. The paresthesias may be evoked or exacerbated by neck flexion (Lhermitte symptom). In one of our patients there was impairment of vibratory and position sense in the legs but no weakness. The sensory abnormalities disappear after a few months and, according to Jones, are not followed by the delayed progressive radiation myelopathy (see below). The pathology has not been fully elucidated, but there is said to be a spongy appearance of the white matter with demyelination and depletion of oligodendrocytes.

Delayed Progressive Radiation Myelopathy This, the most dreaded complication of radiation therapy, is a progressive myelopathy that follows, after a characteristic latent period, the irradiation of malignant tissues in the vicinity of the spinal cord. The incidence of this complication is difficult to determine because many patients die of their malignant disease before the cord lesion matures, but it is estimated to be between 2 and 3 percent (Palmer). According to [Douglas et al](#), patients who have undergone hyperthermia as a treatment for cancer are particularly vulnerable to radiation myelopathy.

Clinical Features The neurologic disorder first appears many months after the course of radiation therapy, practically always after 6 months and usually between 12 and 15 months (latent periods as long as 60 months or even longer have been reported). The onset is insidious, usually with sensory symptoms—paresthesias and dysesthesias of the feet or a Lhermitte phenomenon, and similar symptoms in the hands in cases of cervical cord damage. Weakness of one or both legs usually follows the sensory loss. Initially, local pain is notably absent, in distinction to the effects of spinal metastases. In some cases, the sensory abnormalities are transitory; more often, additional signs make their appearance and progress, at first rapidly and then more slowly and irregularly, over a period of several weeks or months, with involvement of the corticospinal and spinothalamic pathways. Originally, the neurologic disturbance may take the form of a Brown-Séquard syndrome, but with progression it takes the form of a transverse myelopathy, with a spastic paraplegia, sensory loss below a level on the trunk, and sphincteric disturbance.

Reagan and coworkers, who have had a large experience with radiation myelopathy at the Mayo Clinic (1 percent of all cases of myelopathy were of this type), describe yet another myelopathic radiation syndrome—namely, a slowly evolving amyotrophy, with weakness and atrophy of muscles and areflexia in parts of the body supplied by anterior horn cells of the irradiated spinal segments. Most patients with this form of the disease die within a year of onset. Knowledge of the pathology is incomplete.

The CSF in delayed progressive radiation myelopathy is normal except for a slight elevation of protein content in some cases. MRI demonstrates an abnormal signal intensity, decreased in T1-weighted and increased in T2-weighted images. Early in the course of the myelopathy the cord may be swollen and there is often enhancement with gadolinium infusion. The cord lesion corresponds to the irradiated portal, which can be identified precisely by the radiation effect on the marrow of the vertebral bodies. The spinal cord lesion tends to be more extensive than the usual vascular or demyelinative lesion. These are important points to establish, because a mistaken diagnosis of intraspinal tumor may lead to another operation or further irradiation of an already damaged cord.

Pathologic Findings In the spinal cord, corresponding with the level of the irradiated area and extending over several segments, there is an irregular zone of coagulation necrosis involving both white and gray matter, the former to a greater extent than the latter. Varying degrees of secondary degeneration are seen in the ascending and descending tracts. Vascular changes—necrosis of arterioles or hyaline thickening of their walls, with thrombotic occlusion of their lumens—are prominent in the most severely damaged portions of the cord. Most neuropathologists have attributed the parenchymal lesion to the blood vessel changes; others believe that the degree of vascular change is insufficient to explain the parenchymal change ([Malamud et al](#); [Burns et al](#)). Certainly the most severe parenchymal changes in the cord are typical of infarction; but the insidious onset and slow, steady progression of the clinical disorder and the coagulative nature of the necrosis would then have to be explained by a steady succession of vascular occlusions. Exceptional instances, in which a transverse myelopathy has developed within a few hours (as described by [Reagan et al](#)), are more readily explained by thrombotic occlusion of a larger spinal artery.

Treatment and Prevention It must be kept in mind that radiation myelopathy is an iatrogenic disease and is therefore largely preventable. The tolerance of the adult human spinal cord to radiation—taking into account the volume of tissue irradiated, the duration of the irradiation, and the total dose—has been determined by [Kagan and colleagues](#). These authors reviewed all of the cases in the literature up to 1980 and concluded that radiation injury could be avoided if the total dose was kept below 6000 cGy and was given over a period of 30 to 70 days, provided that each daily fraction did not exceed 200 cGy and the weekly dose was not in excess of 900 cGy. It is noteworthy that in the cases reported by [Sanyal and associates](#), the amount of radiation surpassed these limits. Forewarned with this knowledge, physicians now have the impression that the incidence of this complication is decreasing.

A number of case reports remark on temporary improvement in neurologic function after the administration of steroids. This therapy should be tried, because in some patients the disease process appears, after a time, to be arrested short of complete destruction of all sensory and motor tracts. Claims have also been made of regression of early symptoms in response to the administration of heparin split products.

Neurologists attached to tumor treatment centers are sometimes confronted with the late development (up to 10 to 15 years after radiation) of a slowly progressive sensorimotor paralysis of a limb (motor weakness predominates). The condition raises questions of recurrent tumor or the development of a local sarcoma, but the absence of a mass lesion and of pain and the signs on neurologic examination are most consistent with a regional interstitial fibrosing neuropathy. Examples that we have seen are multiple cranial neuropathies after radiation of nasopharyngeal tumors, cervical and especially brachial neuropathies after laryngeal and breast cancers, and lumbosacral plexopathies with pelvic tumors. These are discussed further in [Chap. 46](#).

Spinal Cord Injury due to Electric Currents and Lightning

Among acute physical injuries to the spinal cord, those due to electric currents and lightning should be mentioned. They can also injure the brain and peripheral nerves. These effects are noted briefly, since they are infrequent. It is the spinal cord, however, that is most severely damaged.

Electrical Injuries In the United States, inadvertent contact with an electric current causes about 1000 deaths annually and many more nonfatal but serious injuries. About one-third of the fatal accidents result from contact with household currents, indicating the vulnerability of most of the population to this type of injury.

The factor that governs the damage to the nervous system is the amount, or amperage, of the current with which the victim has contact, not simply the voltage, as is generally believed. In any particular case, the duration of contact with the current and the resistance offered by the skin (this is greatly reduced if the skin is moist or a body part is immersed in water) are of critical importance. The physics of electrical injuries is much more complex than these brief remarks indicate (for a full discussion, see reviews by [Panse](#) and by [Winkelman](#)).

Any part of the peripheral or central nervous system may be injured by electric currents and lightning. The effects may be immediate, which is understandable, but of greater interest are the instances of neurologic damage that occur after a delay of 1 day to 6 weeks (1 week on the average). The immediate effects are apparently the result of direct heating of the nervous tissue, but the pathogenesis of the delayed effects is not well understood. They have been attributed to vascular occlusive changes induced by the electric current, a mechanism that seems to underlie the delayed effects of radiation therapy (see above). However, the latent period of radiation myelopathy is measured in many months rather than in days and the course is more often progressive than self-limited. Moreover, the few postmortem studies of myelopathy due to electrical injury have disclosed a widespread demyelination of long tracts, to the point of tissue necrosis in some segments, and relative sparing of the gray matter, but no abnormalities of the blood vessels.

A rare syndrome of focal muscular atrophy, occurring after an electric shock, has been described by [Panse](#) under the title of *spinal atrophic paralysis*. It occurs when the path of the current, usually of low voltage, is from arm to arm (across the cervical cord) or arm to leg. Pain and paresthesias occur immediately in the involved limb, but these symptoms are transient. Weakness, also unilateral, is immediate as well, followed in several weeks or months by muscle wasting, most often taking the form of segmental muscular atrophy; occasionally the syndrome simulates that of amyotrophic lateral sclerosis or transverse myelopathy (most patients have some degree of weakness and spasticity of the legs). In contrast to injuries due to high-tension current, which affects mainly the spinal white matter (see above), it is mainly the gray matter that is injured in cases of spinal atrophic paralysis, at least as judged from experimental studies.

When the head is one of the contact points, the patient may become unconscious or suffer tinnitus, deafness, or headache for a short period following the injury. In a small number of surviving patients, after an asymptomatic interval of days to months, there has been an apoplectic onset of hemiplegia with or without aphasia or a striatal or brainstem syndrome, presumably due to thrombotic occlusion of cerebral vessels with infarction of tissue.

Lightning Injuries The factors involved in injuries from lightning are less well defined than those from electric currents, but the effects are much the same. The risk of being struck by lightning is about thirty times greater in rural areas than in cities. Direct strikes are often fatal; nearby strikes produce the neurologic damage described below. Prominences such as trees, hills, and towers are struck preferentially, so these should be avoided; a person caught in the open should curl up on the ground, lying on one side with legs close together.

Arborescent red lines or burns on the skin indicate the point of contact of lightning, but the path through the body can be deduced only approximately from the clinical sequelae. Death is due to ventricular fibrillation or to the effects of intense desiccating heat on vital regions of the brain. Lightning that strikes the head is particularly dangerous, proving fatal in 30 percent of cases. Persons struck by lightning are initially unconscious, irrespective of where they are struck. In those who survive, consciousness is usually regained rapidly and completely. Rarely, unconsciousness or an agitated-confusional state may persist for a week or two. There is usually a disturbance of sensorimotor function of a limb or all the limbs, which may be pale and cold or cyanotic. As a rule, these signs are also evanescent, but in some instances they persist, or an atrophic paralysis of a limb or part of a limb makes its appearance after a symptom-free interval of several months. Persistent seizures are surprisingly rare.

MYELITIS

In the nineteenth century, almost every disease of the spinal cord was labeled *myelitis*. Morton Prince, writing in *Dercum's Textbook of Nervous Diseases* in 1895, referred to traumatic myelitis, compressive myelitis, and so on, obviously giving a rather imprecise meaning to the term. Gradually, however, as knowledge of neuropathology advanced, one disease after another was removed from this category until only the truly inflammatory ones remained.

Today the spinal cord is known to be the locus of a limited number of infective and noninfective inflammatory processes, some causing selective destruction of neurons, others affecting primarily white matter (tracts), and yet another group involving the meninges and white matter or leading to a necrosis of both gray and white

matter. The currently accepted term for all these inflammatory conditions is *myelitis*. Other special terms are used to indicate more precisely the distribution of the process: if it is confined to gray matter, the proper expression is *poliomyelitis*; if to white matter, *leukomyelitis*. If the whole cross-sectional area of the cord is involved, the process is said to be a *transverse myelitis*; if the lesions are multiple and widespread over a long vertical extent, the modifying adjectives *diffuse* or *disseminated* are used. The term *meningomyelitis* refers to combined inflammation of meninges and spinal cord, and *meningoradiculitis*, to combined meningeal and root involvement. An inflammatory process limited to the spinal dura is called *pachymeningitis*; and if infected material collects in the epidural or subdural space, it is called *epidural spinal abscess* or *granuloma*, as the case may be. The adjectives *acute*, *subacute*, and *chronic* denote the tempo of evolution of myelitic symptoms—more or less within days, 2 to 6 weeks, or more than 6 weeks, respectively.

Classification of Inflammatory Diseases of the Spinal Cord

- I. Viral myelitis ([Chap. 33](#))
 - A. Enteroviruses (groups A and B Coxsackie virus, poliomyelitis, others)
 - B. Herpes zoster
 - C. Myelitis of AIDS
 - D. Epstein-Barr virus (EBV), cytomegalovirus (CMV), herpes simplex
 - E. Rabies
 - F. Japanese B virus
 - G. HTLV-1 (tropical spastic paraparesis)
- II. Myelitis secondary to bacterial, fungal, parasitic, and primary granulomatous diseases of the meninges and spinal cord
 - A. *Mycoplasma pneumoniae* ([Chap. 32](#))
 - B. Lyme disease
 - C. Pyogenic myelitis
 1. Acute epidural abscess and granuloma
 2. Abscess of spinal cord
 - D. Tuberculous myelitis ([Chap. 32](#))
 1. Pott's disease with spinal cord compression
 2. Tuberculous meningomyelitis
 3. Tuberculoma of spinal cord
 - E. Parasitic and fungal infections producing epidural granuloma, localized meningitis, or meningomyelitis and abscess ([Chap. 32](#))
 - F. Syphilitic myelitis ([Chap. 32](#))

 - E. Paraneoplastic myelopathy and poliomyelitis ([Chap. 31](#))

From this outline it is evident that many different and totally unrelated diseases are under consideration and that a general description cannot possibly encompass such a diversity of pathologic processes. Many of the myelitides are considered elsewhere in this volume in relation to the diseases of which they are a part. Here it is only necessary to comment on the three principal categories and to describe a few of the common subtypes.

Myelitis due to Viruses

The enteroviruses, of which Coxsackie and poliomyelitis are examples, herpes zoster, and AIDS are the important members of this category. The enteroviruses have an affinity for neurons of the anterior horns of the spinal cord and motor nuclei of the brainstem (i.e., they are poliomyelitides), and herpes zoster virus for the dorsal root ganglia; hence the disturbances of function are in terms of motor and sensory neurons, respectively, not of spinal tracts. The onset of these conditions is acute and features a febrile meningomyelitis (see [Chap. 33](#)). Although there are systemic symptoms and sometimes cutaneous ones (in the case of zoster), it is the nervous system disorder that is most significant. The patient suffers the immediate effects of nerve cell destruction, and improvement nearly always follows as altered nerve cells recover. Later in life, possibly as the neuronal loss of aging occurs in the anterior horns and dorsal root ganglia, there may be an increased loss of strength in muscles originally weakened by poliomyelitis ("postpolio syndrome").

The rapid expansion of knowledge of herpesvirus infections has added a new chapter to the viral myelitides. Relatively rare examples of myelitis due to herpes simplex virus (HSV types 1 and 2), varicella-zoster virus (VZV), cytomegalovirus (CMV), Epstein-Barr virus (EBV), and SV70 virus (epidemic conjunctivitis) have been reported, some in patients with immunodeficiency states, particularly HIV infections. The situation is more complex clinically, since most of these agents may also produce a postinfectious variety of myelitis, described further on in this chapter and in [Chap. 33](#) and [Chap. 36](#). In HSV type 2 infections, there may also be an acute lumbosacral radiculitis with urinary retention; and in VZV infections, a sensory ganglionitis, vasculitis, or encephalitis. There is, in a few cases, evidence of an extensive inflammatory necrosis of the spinal cord with involvement of sensory and motor tracts. In other words, these conditions may at times simulate acute paraplegic and quadriplegic transverse or panmyelitis syndromes of nonviral type. However, pleocytosis and isolation of portions of the viral DNA by the polymerase chain reaction or direct culture from the cerebrospinal fluid (CSF) confirm the diagnosis of a primary viral infection, as discussed in [Chap. 33](#) (see [Dawson and Potts](#)).

Affection of the white matter, with sensory and motor paralysis below the level of a lesion, has been reported in so-called dumb rabies (in contrast to the usual form of "mad" or "furious" rabies encephalitis), zoster and simplex myelitis, EBV myelitis, and an infection transmitted by the bite of a monkey, called the *B virus*. Each of these is decidedly rare. Far more common is the myelopathy of AIDS; much rarer is the myelopathy of spinal spastic paraparesis (HTLV-1). With these exceptions, one may say that any myelitis that expresses itself by dysfunction of motor and sensory tracts will usually prove not to be viral in origin but due rather to one of the disease processes in category II or III of the preceding classification. The unique vacuolar myelopathy of AIDS and the myelopathy of human HTLV infections are described below and also in [Chap. 33](#).

There are other rare forms of poliomyelitic reactions of unknown, presumably viral etiology. One such condition presents as an acute febrile meningomyelitis and leaves all the limbs paralyzed and flaccid, sparing the brainstem and affecting the diaphragm to a variable extent. Several such patients have harbored a carcinoma or Hodgkin disease, and the pathology proved to be like that of a poliomyelitic viral infection rather than the usual paraneoplastic syndromes. We have cared for several others who have had destruction of anterior horn cells due apparently to an enterovirus other than poliomyelitis virus (see further on and page 809 and [Fig. 33-4](#)).

Vacuolar Myelopathy with AIDS As the neurology of AIDS has been elucidated, this new clinical and pathologic entity has emerged. Its frequency is impressive—20 of 89 successive cases of AIDS on whom a postmortem examination was performed ([Petito et al](#)). Often the clinical symptoms and signs of spinal cord disease are obscured by a neuropathy or one or more of the cerebral disorders that complicate AIDS—due either to HIV or to an opportunistic infection (CMV disease, toxoplasmosis, etc.). In five cases of severe vacuolar myelopathy in Petito's series, there was leg weakness or leg and arm weakness, often asymmetrical and developing over a period of weeks, to which the signs of sensory tract involvement and sphincteric disorder were added. A sensory ataxia has been a common early feature in our experience. The CSF shows a small number of lymphocytes, a slight elevation of protein, and, occasionally, bizarre giant cells. The white matter of the spinal cord is vacuolated, most severely in thoracic segments. Posterior and lateral funiculi are affected diffusely without confinement to discrete sensory or motor systems. Axons are involved to a lesser degree than myelin sheaths, and lipid-laden macrophages are present in abundance. Similar vacuolar lesions may be seen in the brain in some cases. Although the lesions in the spinal cord resemble those of subacute combined degeneration, levels of vitamin B₁₂ and folic acid have been normal. A similar lesion was seen in one of our cases of chronic lupus erythematosus. Often there are coexistent features of AIDS dementia or one of the several neuropathies that occur in the intermediate and advanced stages of the disease (discussed in [Chap. 33](#)). The antiretroviral drugs that slow the progress of AIDS seem to have little effect on the myelopathy, and one can only resort to the symptomatic treatment of spasticity.

Tropical Spastic Paraparesis due to Human T-Cell Lymphotropic Virus Type I (HTLV-1) The tropical myeloneuropathies were drawn to the attention of neurologists 45 years ago through the observations and writings of Cruickshank. However, it is only relatively recently that a chronic infective-inflammatory disease of

the spinal cord due to the retrovirus HTLV-I has been discovered. The clinical implications of this discovery are broad and extend even to the demyelinating and possibly the degenerative diseases.

Spinal cord disease of this type has been reported from the Caribbean islands, southern United States, southern Japan, South America, and Africa. The clinical picture is one of a slowly progressive paraparesis with increased tendon reflexes and Babinski signs; disorder of sphincteric control is usually an early change. Paresthesias, reduced vibratory and position senses, and ataxia have been described. A few of the patients have had an associated polyneuropathy, as in Cruikshank's early cases. The upper extremities are usually spared (except for lively tendon reflexes), as are cerebral and brainstem structures.

The CSF contains small numbers of lymphocytes of T type (10 to 50 per cubic millimeter), normal concentrations of protein and glucose, and an increased content of IgG with antibodies to HTLV-I. The diagnosis is confirmed by the detection in the serum of the antibodies to the virus. Thinness of the spinal cord is evident on MRI, and subcortical cerebral white matter lesions may be seen as well. Neuropathologic study has documented an inflammatory myelitis with focal spongiform, demyelinating, and necrotic lesions, perivascular and meningeal infiltrates of inflammatory cells, and focal destruction of gray matter. The posterior columns and corticospinal tracts are the main sites of disease, most evident in the thoracic cord. It is strongly suspected but not established that the disease is due to the cytotoxic effect of the viral infection, but an alternative theory of autoimmune damage has been proposed.

The clinical picture can easily be confused with that of progressive spastic paraplegia of the hereditary variety, sporadic motor neuron disease, or the chronic phase of multiple sclerosis. There are also similarities with the AIDS myelopathy described above, but the other features of HIV infection are absent. Tropical spastic paraparesis and HTLV-I are also considered in the chapter on viral disease (page 806). There are anecdotal reports of improvement with intravenous administration of gamma globulin.

Myelitis Secondary to Bacterial, Fungal, Parasitic, and Granulomatous Diseases

With few exceptions, this class of spinal cord disease seldom offers any difficulty in diagnosis. The CSF often holds the clue to causation. In most cases, the inflammatory reaction of the spinal meninges is only one manifestation of a generalized (systemic) disease process. The spinal lesion may involve primarily the pia-arachnoid (leptomeningitis), the dura (pachymeningitis), or the epidural space, e.g., taking the form of an abscess or granuloma; in the last circumstance, damage to the spinal cord is due to compression and ischemia. In some acute forms, both the spinal cord and meninges are simultaneously affected, or the cord lesions may predominate. Chronic spinal meningitis may involve the pial arteries or veins; as the inflamed vessels become thrombosed, infarction (myelomalacia) of the spinal cord results. Chronic meningeal inflammation may provoke a progressive constrictive pial fibrosis (so-called spinal arachnoiditis) that virtually strangulates the spinal cord. In certain instances, spinal roots become progressively damaged, especially the lumbosacral ones, which have a long meningeal course. Posterior roots, which enter the subarachnoid space near arachnoid villi (where CSF is resorbed), tend to suffer greater injury than anterior ones (as happens in tabes dorsalis). Interestingly, there are many cases of chronic cerebrospinal meningitis that remain entirely without symptoms until the spinal cord or roots become involved.

The unique myelitis caused by the atypical pneumonia agent *Mycoplasma pneumoniae* has been conceptualized as a postinfectious immune disease, as discussed on pages 747 and 975. However, portions of the DNA from this organism have been found in the spinal fluid early in the course of illness (using the polymerase chain reaction), suggesting instead a direct bacterial infection of the spinal cord (see [Chap. 32](#)). It is not known whether antibiotic treatment alters the course of the illness.

Syphilitic myelitis is discussed on page 787. *Abscess of the spinal cord* (acute bacterial myelitis) is exceedingly rare and is only beginning to be recognized by MRI. At times it stands as a single pyogenic metastasis, but more often there has been spread from a contiguous infected surgical site or a fistulous connection with a superficial abscess or furuncle. *Acute spinal epidural abscess and granuloma* are the more important representatives of this group.

Sarcoid may present as an intramedullary spinal cord mass, as in the cases of [Levivier and colleagues](#). More often the granulomatous lesion, which may be focal or multifocal, simulates demyelinating disease, with respect to its tendency to relapse and remit and an apparent response to corticosteroids (page 761). An asymmetrical ascending paraparesis and bladder disturbance have been the features in our patients. Usually there is evidence of disseminated sarcoidosis and the CSF is abnormal (increase in cells and protein), but we have encountered several instances of sarcoid restricted to the spinal cord before it was clinically evident in the chest (chest CT will generally demonstrate hilar adenopathy). Elevation of the spinal fluid IgG concentration and the presence of oligoclonal bands are typical but not constant in these cases of neurosarcoidosis, and often there are activated histiocytes in the CSF. The use of angiotensin-converting enzyme levels in the CSF to distinguish sarcoidosis from multiple sclerosis suffers from the lack of normative values for this test, but it is said to be elevated in two-thirds of patients. The MRI is invariably abnormal and the conus may show intramedullary lesions, but the most characteristic finding is a nodular enhancement of the meninges adjacent to a lesion of the cord or nerve roots, similar to that observed in neoplastic meningitis. The diagnosis can be confirmed by mediastinal lymph node biopsy or by the less desirable method of biopsy of the spinal meninges and subpial cord.

A number of other rare granulomatous conditions have on occasion caused an intrinsic or, more often, an extrinsic compressive myelopathy, including brucellosis, xanthogranulomatosis, and eosinophilic granuloma. The diagnosis may be suspected if the systemic disease is apparent at the time, but in some instances only the histology of a surgical specimen reveals the underlying process.

Spinal Epidural Abscess This process is worthy of emphasis because the diagnosis is often missed or mistaken for another disease, with disastrous results. Children or adults may be affected. Infection of the epidural space has a wide variety of sources. An injury to the back, often trivial at the time, furunculosis or other skin or wound infection, or a bacteremia may permit seeding of the spinal epidural space or of a vertebral body. This gives rise to osteomyelitis with extension to the epidural space. Occasionally, extension is from an infected disc. An epidural abscess or granuloma may also develop in the course of a septicemia or in an addict following the use of nonsterile needles or the injection of contaminated drugs. In other cases organisms may be introduced into the epidural space during spinal surgery or rarely via a lumbar puncture needle during epidural or spinal anesthesia or epidural injections of steroid or other therapeutic agents. The localization in these latter instances is over lumbar and sacral roots. In the cases of *cauda equina epidural abscess*, back pain may be severe and neurologic symptomatology minimal unless the infection extends upward to the upper lumbar and thoracic segments of the spinal cord. *Staphylococcus aureus* is the most frequent etiologic agent, followed by streptococci, gram-negative bacilli, and anaerobic organisms.

At first, the suppurative process is accompanied only by fever and pain, usually intense, in the back, followed within a day or several days by radicular pain in most cases. Headache and nuchal rigidity are sometimes present; more often there is persistent pain and a disinclination to move the back. After several more days, there is the onset of a rapidly progressive paraparesis and paraplegia or quadriplegia, associated with sensory loss in the lower parts of the body and sphincteric paralysis with urinary and fecal retention. Percussion of the spine elicits tenderness over the site of the infection. Examination discloses all the signs of a complete or partial transverse cord lesion, with elements of spinal shock if paralysis has evolved rapidly. The CSF contains a relatively small number of white cells (usually fewer than 100 per cubic millimeter), both polymorphonuclear leukocytes and lymphocytes, unless the needle penetrates the abscess, in which case pus is obtained. The protein content is relatively high (100 to 400 mg/100 mL or more), but the glucose is normal. An elevation of the sedimentation rate and a peripheral neutrophilic leukocytosis are important clues (often neglected) to the diagnosis ([Baker et al](#)).

The foregoing clinical and spinal fluid findings call for immediate MRI imaging or CT, the latter preferably with myelography, to determine the level of the infected mass. If not treated surgically by laminectomy and drainage at the earliest possible time, before the onset of paralysis, the spinal cord lesion, which is due in part to ischemia (compression mainly of veins), becomes more or less irreversible. Antibiotics in large doses must also be given. Cauda equina epidural abscess without neurologic signs may in many cases be treated solely with antibiotics, although some surgeons favor drainage, which must be undertaken in any case if osteomyelitis develops. When osteomyelitis of a vertebral body is the primary abnormality, the epidural extension may implicate only a few spinal sensory and motor roots, leaving long tracts and other intramedullary structures intact. In some cases with cervical epidural abscesses, stiff neck, fever, and deltoid-biceps weakness are the main neurologic abnormalities.

A slowly progressive and then stabilizing syndrome of incomplete cord compression may occur after apparently successful drainage of an epidural abscess. This is usually caused by the formation of a fibrous and granulomatous reaction at the operative site. Distinguishing this inflammatory mass from residual epidural abscess may be quite difficult, even with enhanced MRI, but persistent fever, leukocytosis, and an elevated sedimentation rate should suggest that surgical drainage of the abscess was incomplete.

Spinal subdural bacterial infections also occur and, clinically, are virtually indistinguishable from epidural ones. A clue is provided by the CT myelogram, in which the subdural lesion has a less sharp margin and a greater vertical extent. The difference is also appreciated on axial MRI. The epidural and subdural infections, if they smolder owing to delayed diagnosis or inadequate therapy, may evolve into a chronic adhesive meningomyelitis.

Subacute pyogenic infections and *granulomatous infections* (tuberculous, fungal) may also arise in the spinal epidural space. The clinical picture is less dramatic, and local and radicular pain is slight or absent; the diagnosis depends on the demonstration, in a patient with weakness and sensory loss below a certain level on the trunk, of a partial or complete block by CT myelography and MRI. Osteomyelitis may not be seen for a time in plain films, but bone scans and MRI are revealing. Treatment depends on the nature of the underlying disease and the general condition of the patient.

Spinal Cord Abscess This entity was first described by Hart in 1830 and, although it is rare, 73 cases had been reported by 1994 ([Candon and Frerebeau](#)). In some instances the patient was known to have had a systemic bacterial infection, a septicemia, or endocarditis; in others there was a contiguous abscess in the skin or subcutaneous tissues with a fistula to the spinal cord through an intervertebral foramen. Spinal cord abscess is a rare complication of spinal dysraphism or of a developmentally open fistulous tract. The symptoms are indistinguishable from those of epidural abscess—namely, spinal and radicular pain followed by sensory and motor paralysis; the CSF findings are also the same. Woltman and Adson described a patient in whom surgical drainage of an encapsulated intramedullary abscess led to recovery, and Morrison and associates reported a similar case caused by *Listeria monocytogenes*, which was successfully drained and the meningeal infection suppressed by ampicillin and chloramphenicol. MRI is the most useful diagnostic procedure.

Tuberculous Myelitis Solitary tuberculoma of the spinal cord as part of a generalized infection is an extreme rarity. Tuberculous osteitis of the spine with kyphosis (Pott's disease) is more frequent; pus or caseous granulation tissue may extrude from an infected vertebra and gives rise to an epidural compression of the cord (Pott's paraplegia). Occasionally a tuberculous meningitis may result in pial arteritis and spinal cord infarction. The paraplegia may appear before the tuberculous meningitis is diagnosed.

All these forms of tuberculosis have become infrequent in the United States and western Europe. Additional comments can be found on page 759.

Meningomyelitis due to Fungus and Parasitic Diseases A wide variety of fungal and parasitic agents may involve the spinal meninges. Such infections are rare, and some do not occur at all in the United States or are limited to certain geographic areas, particularly among immigrant populations. *Actinomyces*, *Blastomyces*, *Coccidioides*, and *Aspergillus* may invade the spinal epidural space via intervertebral foramina or by extension from a vertebral osteomyelitic focus. *Cryptococcus*, which causes meningoencephalitis and rarely a cerebral granuloma, in our experience seldom causes spinal lesions. Hematogenous metastases to the spinal cord or meninges may occur in both blastomycosis and coccidioidomycosis. Occasionally an echinococcal infection of the posterior mediastinum may extend to the spinal canal (epidural space) via intervertebral foramina and compress the spinal cord.

Schistosomiasis (bilharziasis) is a recognized cause of myelitis in the Far East, Africa, and South America. The spinal cord is a target for all three common forms of *Schistosoma*: *S. haematobium*, *S. japonicum*, and *S. mansoni*, but particularly the last of these (see page 780). The schistosomal ova evoke a granulomatous myelomeningoradiculitis. The lesions are destructive of gray and white matter, with ova in arteries and veins leading to obstruction and ischemia (Scrimgeour and Gajdusek). Less often, a localized granuloma gives rise to a compressive cord syndrome and, rarely, the disease takes the form of an acute transverse myelitis with massive necrosis of cord tissue ([Queiroz et al](#)). We have studied two patients in whom the spinal cord in the low thoracic and lumbar region was infected approximately 3 weeks after they swam in contaminated water during an African vacation. The CSF showed only a slight elevation of protein, and there was no abnormality in the myelogram. The administration of praziquantel arrested the course of the illness, but the patients were left disabled.

Myelitis of Noninfectious Inflammatory Type (Acute Transverse Myelitis)
